Although the relationship between intentions and turnover appears to be consistent and generally stronger than the satisfaction–turnover relationship, it accounts for less than 24% of the variance in turnover. Among the possible reasons for this are that intentions do not account for impulsive behavior, that they do not adequately capture the perception and evaluation of alternatives, and that along with personal, organization, and external conditions, they may change between original measurement and the observation of actual behavior. The more specific the behavioral intention statement and the less time its measurement and the behavior, the stronger the relationship should be. However, as Graen and Ginsburgh (1977) noted,

Table 9
Studies of Relations Between Intentions and Turnover

Factor	Population	N	Relation to turnover
Behavioral intentions			
Kraut (1975)	Salesmen	911	Lower intent to remain significantly associated with turnover after 18 months, $p < .01$; between 18 and 60 months, $p < .05$ ($n = 791$; $r = -.17$* for voluntary turnover in both short- and long-term cases
Mangione (Note 2)	Institute for Social Research diverse occupational sample	242	Intentions significantly related to turnover, $p < .001$ (over 2 years)
Marsh & Mannari (1977)	Japanese electrical company employees	1,033	$\tau\text{-}b = -.13$* (4 years)
Mobley, Horner, & Hollingsworth (1978)	Hospital employees	203	$r = .49$* for intention to quit (47 weeks); $r = .29$* for intention to search; $r = .19$* for thinking of quitting
Newman (1974)	Nursing home employees	108	$r = .39$* (over 2 months)
Waters, Roach, & Waters (1976)	Insurance company clerical	105	$r = -.42$* (over 2 years with intent to remain) $r = .36$* (with biographical data partialed out)
Attitude toward act of quitting			
Newman (1974)	Nursing home employees	108	$r = .30$*
Normative beliefs re quitting			
Newman (1974)	Nursing home employees	108	$r = .32$*

* $p < .01$.

Table 10
Studies of Relations Among Organizational Commitment, Involvement, Job Attachment, and Turnover

Factor	Population	N	Relation to turnover
Organizational commitment			
Marsh & Mannari (1977)	Japanese electrical company employees	1,033	$r = -.09^*$, but no significant contribution in multiple regression with 15 other variables
Porter, Steers, Mowday, & Boulian (1974)	Psychiatric technicians	60	Commitment had largest standardized weight in discriminant function, which included Job Descriptive Index
Porter, Crampon, & Smith (1976)	Management trainees	32	$r = .41^*$ for Day 1 measure; $r = .43^*$ for measure in last 2 months with turnover data over 15 months; decline in commitment prior to actually leaving
Steers (1977)	Hospital employees	382	$r = -.17^{**}$ (1 year); commitment and intention to remain, $r = .31^{**}$; desire to remain, $r = .44^{**}$
Organizational involvement			
Mirvis & Lawler (1977)	Bank tellers	160	$r = -.29^{**}$ (3 months)
Job attachment			
Koch & Steers (1978)	Nonmanagerial entry-level public agency employees	77	$r = -.38^{**}$; $r = -.40^{**}$ with satisfaction partialed out

$^* p < .05.$ $^{**} p \leq .01.$

the more specific the intention measure and the closer the person is to actually quitting, the more trivial the prediction. Additionally, without analyses of the precursors of intentions, little knowledge of the psychology of turnover behavior is generated.

Also included in Table 9 are two variables related to intentions in the Fishbein (1967) model: attitude toward the act of quitting and normative beliefs regarding quitting. The Newman (1974) study is one of the few that tests the Fishbein model with a turnover criterion. Both variables, as well as intentions, were significantly related to turnover.

It is evident that intentions are a significant variable in the turnover process. However, additional research is required on the antecedent and covariates of intentions, the manner in which intentions change over time, and the reasons for the lack of a stronger relationship between intentions and turnover.

Organizational commitment, involvement, and job attachment. A number of researchers have recently focused on the antecedents and consequences of organizational commitment (see, e.g., Porter et al. 1974; Steers, 1977). Porter et al. (1974, p. 604) defined organizational commitment as a more global evaluative linkage between the employee and the organization, which includes job satisfaction among its components. More specifically, organizational commitment was defined as the strength of an individual's identification with and involvement in a particular organization and is characterized by (a) a strong belief in and acceptance of an organization's goals and values, (b) a willingness to exert considerable effort on behalf of the organization, and (c) a definite desire to maintain organizational membership. Porter et al. stated that intention to remain is a component of commitment.

More recently, Koch and Steers (1978) suggested that job attachment may be a primary precursor of turnover. They defined job attachment as an attitudinal response to one's job characterized by (a) a congruence between one's real and ideal jobs, (b) an identification with one's chosen occupation, and (c) a reluctance to seek alternative employment. Koch and Steers further noted that job attachment is clearly related to organizational commitment, although it focuses more specifically on one's occupation or job than on the organization as a whole, that job attachment should be more closely related to turnover than is satisfaction because of its conative or intentional component, and that it should be influenced relatively more by individual than by job characteristics.

Table 10 summarizes recent studies of the relation between these variables and turnover. Porter et al. (1974), Porter et al. (1976), and Steers (1977) all found that commitment was more significantly and negatively related to turnover than was satisfaction. Marsh and Mannari (1977) discovered a significant but weak negative correlation between commitment and turnover among Japanese employees, whereas Mirvis and Lawler (1977) observed that organizational involvement, one component of commitment, was significantly and negatively related to turnover.

Koch and Steers (1978) found job attachment to be significantly and negatively related to turnover. It should be noted that role orientation in the previously reviewed Graen et al. (1973) and Graen and Ginsburgh (1977) studies (perceived relevance of the job for the worker's career) is related to at least one aspect of Koch and Steers's definition of job attachment. The Graen studies found role orientation to be significantly and negatively related to turnover.

The developing body of research on commitment and attachment suggests that these concepts are significantly and negatively related to turnover and more strongly related to turnover than to satisfaction. However, both commitment and attachment, as defined in the research cited above, are such complex constructs as to make generalizations rather tenuous. For example, is it the inclusion of intentions in the operational definitions of commitment and attachment that accounts for their improved prediction of turnover? Is it not possible for congruence between individual and organizational goals and values to vary independently of the other two components of commitment? Perhaps a more microanalytic treatment of these constructs

Table 11
Studies of Relations Between Met Expectations and Turnover

Study	Population	N	Relation to turnover
Dunnette, Arvey, & Banas (1973)	College graduates	1,020	Leavers had larger differences than stayers on a Vroom-type (1964) motivation index between expectations and job experiences on last job (significance levels not reported)
Farr, O'Leary, & Bartlett (1973)	Female sewing machine operators	160	White applicants administered a work sample test had lower voluntary turnover than group given traditional tests, $p < .05$; no differences for minority applicants (no direct measure of expectations)
Ilgen & Seely (1974)	New West Point cadets	468	Those receiving booklet of realistic information had lower turnover than control group (no direct measure of expectations and treatment after acceptance decision)
Ilgen & Dugoni (Note 3)	Retail clerks	117	Met expectations was inconsistently related to turnover, although summary met expectations variable was significantly and negatively related to turnover ($r = -.22^{**}$)
Wanous (1973)	New telephone company operators	80	Realistic compared with traditional job preview had lower expectations on Job Descriptive Index Work* and Supervision,** lower thoughts of quitting,** and lower measures on relevant Minnesota Satisfaction Questionnaire items and job survival ($p < .20$)

* $p < .05$. ** $p < .01$.

would prove useful. A model that incorporates some components of commitment and attachment is discussed in a subsequent section.

Met expectations. Porter and Steers (1973) suggested that met expectations provide a conceptual framework for the diverse turnover literature. They viewed this concept as the discrepancy between what a person encounters on the job in the way of positive and negative experiences and what was expected. They predicted that "when an individual's expectations—whatever they are—are not substantially met, his propensity to withdraw would increace" (Porter & Steers, 1973, p. 152).

Since the Porter and Steers review, there have been several studies relevant to the met expectations hypothesis. A subset of these studies dealt with expectations at the time of original organizational entry. Table 11 summarizes studies since the Porter and Steers review that are most relevant to met expectations.

The Dunnette, Arvey, and Banas (1973) study found that leavers exhibited a greater discrepancy between original expectations and actual experiences than did stayers. However, significance levels were not reported and leavers' perceptions of their last job were retrospective, suggesting the possibility of postdecision distortion.

Farr, O'Leary, and Bartlett (1973) and Ilgen and Seely (1974) found some evidence that individuals given realistic information about the job (via a work sample and a booklet) exhibited lower turnover. However, in neither study were expectations or subsequent experiences directly assessed.

Ilgen and Dugoni (Note 3) sought to assess directly the met expectation hypothesis, but found that met expectations were inconsistently related to satisfaction or turnover. Wanous (1973) discovered that a realistic job preview, compared with a more traditional orientation, lowered both expectations and thoughts of quitting, but did not significantly influence turnover.

Direct support of the met expectations hypothesis is rather weak. In an insightful discussion of the conceptual and empirical support for met expectations (particularly as related to realistic job previews), Ilgen and Dugoni concluded that to expect realistic job previews to influence satisfaction, and subsequently turnover, through the mechanism of met expectations is naive. Specifically, the hypothesis is theorized to inadequately reflect individual differences in values. However, it should be noted that Porter and Steers (1973) appeared to account for individual differences through "desired expectations." Ilgen and Dugoni also noted that accurate expectations cannot compensate for deficiencies in the immediate job environment. Additionally, the met expectations hypothesis appears to give insufficient attention to the socialization and assimilation processes.

Although expectations may play an important role in attachment, satisfaction, and turnover, a more complex conceptualization than the met expectations hypothesis appears necessary. One such conceptual model is proposed in a subsequent section of this article.

Multivariate Studies

The preceding sections of this review have repeatedly suggested that multivariate studies are necessary in turnover research. Such studies are necessary in order to interpret the relative efficacy of numerous variables and constructs thought to be related to turnover, to resolve apparently contradictory bivariate studies, to attempt to account for a greater proportion of the variance in turnover, and to move toward a more complete understanding of the turnover process.

Table 12 summarizes recent multivariate studies that have used turnover as the criterion. Graen and Ginsburgh (1977) found that role orientation, leader acceptance, and their interaction accounted for 23% of the variance in university service employee turnover. That the interaction accounted for 6% of the variance suggests that noncompensatory models of turnover may be required.

Mobley et al. (1978) tested a simplified version of a model of possible intermediate linkages between job satisfaction and turnover (Mobley, 1977). Although a number of

Table 12
Summary of Recent Multivariate Studies of Turnover

Study	Population	N	Independent variables and relation to turnover
Graen & Ginsburgh (1977)	University service employees	89	Significant main effects for role orientation (10% variance explained) and leader acceptance (7% variance); significant interaction (6% variance), with resignations at 24 months
Mobley, Horner, & Hollingsworth (1978)	Hospital employees	203	Intention to quit was the only significant regression coefficient ($r^2 = 24\%$) in equation that included intent to search, thinking of quitting, probability of finding acceptable alternative, age, tenure, and satisfaction (47 weeks)
Mangione (Note 2)	Institute for Social Research diverse occupational sample	295	Using 15 demographic, satisfaction, and occupational variables, $R = .63$ (shrunken $r^2 = 22\%$); rank ordered by betas, satisfaction with comfort, satisfaction with co-workers, industry, age, tenure, occupation, satisfaction with financial rewards, occupational prestige, satisfaction with challenge, education, marital status, resource adequacy, race, collar, and sex
Marsh & Mannari (1977)	Japanese electrical company employees	784	$R = .34$ (16 variables); sex, $-.27^{**}$; organizational status, $-.08^{*}$; performance, $.07^{*}$; number previous jobs, $.06^{*}$ (betas); nonsignificant variables: promotion chances, cohesiveness, participation, distance migrated, knowledge of procedures, values, size of community of origin, lifetime commitment, residence, autonomy, and satisfaction
Newman (1974)	Nursing home employees	108	$R = .48^{**}$ for JDI scales, faces scale, attitude toward quitting, normative beliefs regarding quitting, and intentions to quit (not cross-validated; individual betas not reported)
Porter, Steers, Mowday, & Boulian (1974)	Psychiatric technicians	60	Organizational commitment and JDI with age partialed out; significant discriminant function at 2 times closest to actual termination (20.7%) and 21% variance related to termination decision
Waters, Roach, & Waters (1976)	Insurance company clerical	105	$R = 50$, with intentions, JDI work, and tenure the only significant variables; age, other JDI scales, and marital status not significant; intentions accounted for 18% of variance; JDI work and tenure added 7%

Note. JDI = Job Descriptive Index. $^{*}p < .05$. $^{**}p < .01$.

demographic, satisfaction, and perceived alternative measures exhibited significant bivariate relations with turnover, multiple regression analysis revealed intention to quit as the only significant coefficient ($r^2 = 24\%$).

Mangione (Note 2) used 15 demographic, satisfaction, and occupational variables to predict turnover. He found the strongest regression coefficients to be satisfaction with comfort, satisfaction with co-workers, rewards, industry type, age, tenure, occupation, and satisfaction with financial rewards ($r^2 = 40\%$; adjusted $r^2 = 22\%$). Of particular interest was the fact that three different classes of variables (satisfaction, demographic, and occupational) were represented among the strongest regression coefficients. Satisfaction did not subsume the unique variance in the demographic and occupational variables. Unfortunately, this study did not include perception and evaluation of alternatives.

The Marsh and Mannari (1977) study is of particular interest because it dealt with a Japanese sample. These authors found only four variables with significant coefficients (sex, organizational stature, performance, and number of previous jobs). Commitment and satisfaction were among those that did not exhibit significant regression coefficients. This study serves to emphasize the necessity of evaluating models that can generalize beyond the United States and Western industrialized nations.

Newman (1974) conducted one of the few direct tests of the Fishbein (1967) model. Although individual regression coefficients were not reported, he discovered that 23% of the variance in turnover was accounted for by satisfaction, attitude toward quitting, normative beliefs regarding quitting, and actual intentions to quit. The multivariate study by Waters, Roach, and Waters (1976) found a coefficient of 25%. Intentions accounted for 18%, whereas the Job Descriptive Index (JDI) Work scale (Smith, Kendall, & Hulin, 1969) and tenure added the additional 7%.

Porter et al. (1974) observed that organizational commitment and the JDI accounted for 21% of the variance in turnover at two different points in time with age partialed out. Commitment made the stronger contribution.

Several generalizations are possible from these studies. First, each of the studies accounted for more variance in turnover than did satisfaction or any other of the single variables. Thus, satisfaction does not appear to be an adequate composite of other precursors and correlates of turnover. Also, it is evident that intentions, whether measured directly or included in commitment, enhance the prediction of turnover. With the exception of the Mobley et al. (1978) study, other variables when combined with intentions enhanced the prediction. It should be noted that few of the multivariate studies included either perception and evaluation of alternatives or cross-validation. These omissions continue to be major shortcomings of the research.

Summary

Employee turnover remains a frequently researched phenomenon. This is evident from the number of studies since the Porter and Steers (1973) review. Many of these studies have dealt with only a small subset of the variables potentially relevant to turnover, and many are not based on a clear conceptual model. This precludes making strong summary generalizations of the research studies.

Table 13 presents a summary of the Porter and Steers (1973) review, the Price (1977) review, and the present authors' conclusions based on the recent research. In the placement of categories in Table 13 an attempt has been made at maintaining the integrity of the various authors' classification schema and at calling attention to possible overlap in classification groupings. In interpreting the table, *negative* refers to a negative relationship, that is, the higher the variable the lower the turnover, while *positive* refers to a positive relationship. In the case of normal variables, the nature of the relationship is specified.

The qualifiers *consistent*, *moderate*, *weak*, or *inconclusive* are used in Table 13. These qualifiers refer to the consistency with which

a significant relationship was found and to the relative number of studies reporting such a relationship. These qualifiers do not refer to the strength of a relationship in terms of the size of a correlation or variance explained.

The present review, in agreement with the earlier reviews of Porter and Steers and Price, found age, tenure, overall job satisfaction, and reaction to job content to be consistently and negatively associated with turnover. Among the more recently studied variables, intentions and commitment–attachment were found to consistently relate to turnover. Because of the relatively few multivariate studies, an ordering of these variables in terms of relative contribution to turnover is tenuous. However, it appears that intentions and commitment–attachment (which includes intentions) made a stronger contribution to turnover behavior than did satisfaction and demographic variables. Further research is needed for an adequate mapping of the antecedents of intentions.

Moderately consistent support for the negative relationship between supervisory style and turnover was evident, a somewhat more qualified conclusion than that reached by Porter and Steers (1973). Recent research reveals an inconclusive pattern of results with respect to pay, promotion, and peer group relations. These results stand in contrast with the consistent negative generalization of Porter and Steers's review. Differences in the availability of alternatives, the lack of multivariate studies, the lack of multiple measures of perception or affect, and the lack of a clear conceptual model make interpretation of these differences difficult.

The compelling conceptual argument that alternatives are an important variable in the turnover process continues to be supported in aggregate-level studies, but has weak support at the individual level because it has been infrequently studied.

Direct support for the met expectations hypothesis is weak. Although realistic job previews have been shown to be a possible aid in reducing turnover, the psychology of this effect is not well understood.

Finally, the limited number of multivariate studies indicates that greater variance in turnover can be explained by using multiple variables, that a great deal of variance is still unexplained, that inclusion of intentions significantly enhances the prediction of turnover, and that satisfaction is an inadequate summary variable for capturing the effects of other demographic, organizational, occupational, or external variables.

Methodological and Conceptual Comments

Predictive Designs

It is encouraging to note that an overwhelming majority of recent research designs have been predictive rather than retrospective. However, few studies have used repeated measures of the perceptual or affective variables, the Porter et al. (1976) and Graen and Ginsburgh (1977) studies being substantive exceptions. To the extent that turnover is a dynamic process, longitudinal designs with repeated measures should be of high utility.

Linear Models

Most research has been based on the assumptions of a linear and compensatory model. Fleishman and Harris (1962) earlier demonstrated the possibility of a nonlinear relationship between supervisory style and turnover. Mangione (Note 2) was one of the few authors to examine possible nonlinear relationships. Additionally, the Graen and Ginsburgh (1977) finding of a significant interaction between role orientation and leader acceptance calls attention to the need for further exploration of interaction terms.

Criterion

A troublesome issue in turnover research concerns the definition of turnover rates and types of turnover at both the aggregate and individual levels (see Price, 1975–1976, 1977, for an evaluation of a number of aggregate measures of turnover). At the individual level, one of the more troublesome issues is the distinction between voluntary and involuntary turnover. The bulk of the individual-

Recently studied variable			
Intentions to quit			Consistent positive
Commitment/attachment			Consistent negative
Met expectations			Weak negative

level turnover research focuses on voluntary turnover.

Precise definitions of voluntary turnover are infrequently given, and what is included as voluntary may differ across studies. For example, Marsh and Mannari (1977) incorporated pregnancy under voluntary turnover, whereas Mirvis and Lawler (1977) and Waters et al. (1976) excluded pregnancy. The definition of voluntary may well have contributed to Marsh and Mannari's finding of a significant difference in turnover as a function of sex. Much more subtle effects may be associated with results as a function of the definition of voluntary.

The categorization of reasons for turnover is frequently taken from company records. Many personnel practitioners readily admit that a variety of factors influence the administratively recorded reason for attrition. Lefkowitz and Katz (1969) reported significant differences in administrative and self-reported reasons for termination. In agreement with Forrest et al. (1977), further efforts to clarify the implications of different operational measurements of turnovers are appropriate. A multiple measure approach to identifying reasons for turnover would be useful.

Finally, little research has addressed the relationship between voluntary and involuntary turnovers. To assume that these are completely independent phenomena, especially in the case of discipline-related terminations, appears simplistic.

Although turnover is frequently thought of as a "clean" objective criterion, the issues raised above suggest the need for greater attention to the criterion problem in turnover research.

Measures of Satisfaction

In recent years, the JDI (Smith et al., 1969) has become the predominant measure of satisfaction with various facets of the job setting. The majority of satisfaction–turnover studies reviewed in this article used the JDI. The careful development of the JDI is well documented, and there is a clear advantage to using a common satisfaction measure across a variety of studies. However,

overreliance on any single measure raises the possibility that method variance has contaminated supposedly generalizable relationships. As Gillet and Schwab (1975) suggested, it seems prudent to use multiple measures of the same construct wherever possible.

Time

The role of time in turnover research is evident in a number of ways. As noted earlier, there is a consistent negative relationship between tenure (length of time on the job) and turnover. Some studies have ignored tenure, some have partialed out its effect, and others have included it in a multivariate design. Understanding the psychology of the tenure effect is probably best facilitated by the latter treatment.

The time variable is also part of the criterion problem to the extent that different studies measure turnover over different lengths of time. Marsh and Mannari (1977) collected their turnover data over a 4-year period, whereas other studies have looked at turnover over a matter of weeks, for example, Newman (1974). The effect of differing lengths of time between measurement of independent variables and the turnover behavior is infrequently studied. Porter et al. (1976) and Waters et al. (1976) are exceptions. This appears to be a topic in need of additional research.

Finally, the temporal dimension may be relevant to the extent that different variables or combinations of variables exert a differential influence on turnover as a function of stages in the organizational socialization process. Graen and Ginsburgh (1977) discussed this possibility.

Primacy of Work

Turnover is generally conceptualized in terms of demographic, organizational, and individual affective factors and on infrequent occasions in terms of perceived alternatives. While such conceptualizations may reflect individual values relative to the work setting, they do not reflect the importance of work-related values relative to other life values and interests. The work of Dubin and his associates (see, e.g., Dubin, Champoux, & Porter, 1975) has demonstrated that differences in central life interests are related to differences in evaluations of the work environment and in organizational commitment. Marsh and Mannari (1977) found a significant negative relationship between primacy of work values and turnover. It appears that future turnover research should deal not only with the work environment and external alternatives but also with the centrality of work relative to other life values and interests.

Conceptual Model of Employee Turnover

Drawing in part on the review and analysis presented earlier, this section develops a conceptual model of the employee turnover process. A simplified schematic representation of this model is presented in Figure 1. Among the characteristics of this model are the following:

1. It is a model of individual-level turnover behavior. Individual differences in perceptions, expectations, and values are explicitly recognized. Further, individual differences in personal and occupational variables are included.

2. Perception and evaluation of alternative jobs is given explicit treatment.

3. The probable roles of centrality of work values and interests relative to other values and interests, beliefs regarding nonwork consequences of quitting or staying, and contractual constraints are specifically recognized.

4. The possible joint contribution to turnover of job satisfaction (present affect), job attraction (expected future affect), and attraction of attainable alternatives is proposed.

5. Intention to quit is considered to be the immediate precursor of turnover, with impulsive behavior and the time between measurement of intentions and behavior attenuating this relationship.

The rationale for the model is described starting with turnover behavior and working back through its antecedents.

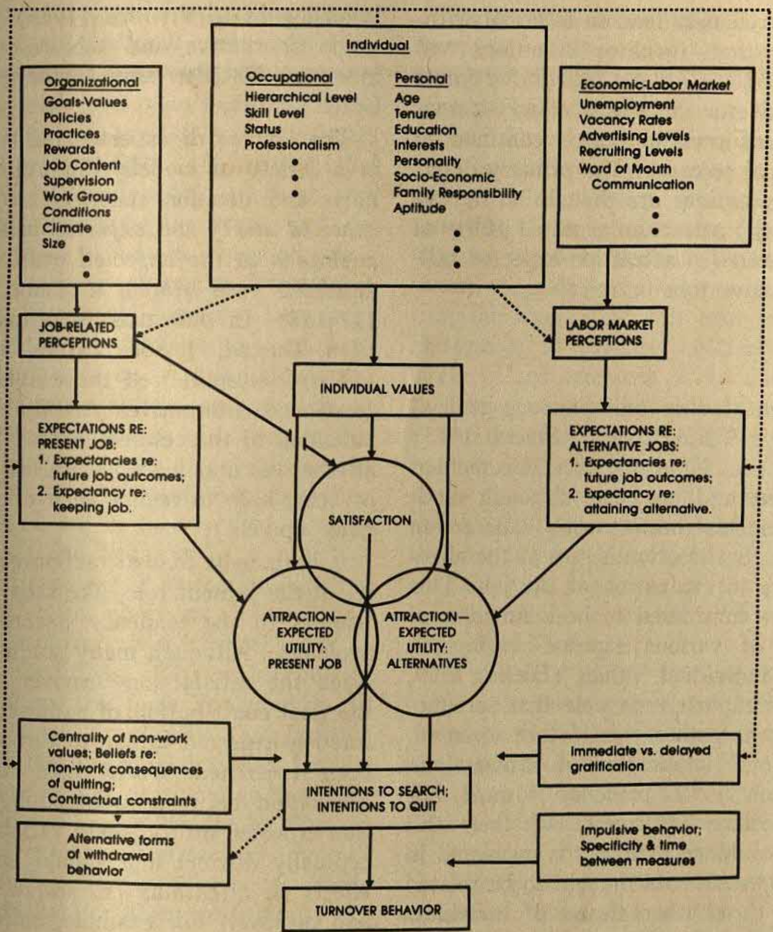

Figure 1. A schematic representation of the primary variables and process of employee turnover.

Intentions

The immediate precursor of behavior is thought to be intentions (Dulaney, 1961, 1968; Fishbein & Ajzen, 1975; Locke, 1968; Mobley, 1977; Ryan, 1970). Therefore, the best predictor of turnover should be intention to quit (see, e.g., Kraut, 1975; Mobley et al., 1978; Newman, 1974; Waters et al., 1976). The relationship between turnover and intention should be stronger the more specific the intention statement and the closer in time the measurement of the intention and the behavior. Impulsive behavior attenuates the intention–behavior relationship.

Graen and Ginsburgh (1977) observed that the more specific and closer to the act the intention measure comes, the more trivial the prediction. Although probably valid, this observation should not be interpreted as indicating that understanding the turnover process is not facilitated by including intentions and evaluating their precursors. Neither should the personnel-planning utility of assessing even more distant intentions (see, e.g., Kraut, 1975) be overlooked.

There are at least two intentions of interest, intention to search and intention to quit. Mobley (1977) suggested that intention to search and search behavior should generally precede intention to quit and turnover. Exceptions include impulsive behavior and nonsolicited attractive alternatives. Lack of perceived attractive alternatives or an un-

successful search may lead to forms of withdrawal other than turnover intentions and behavior. Relations among alternative forms of withdrawal and the effects of no alternative or an unsuccessful search continue to need additional research. The primary determinants of intentions are thought to be (a) satisfaction, (b) attraction expected utility of present job, and (c) attraction expected utility of alternative jobs or roles.

Satisfaction

The present review and previous reviews (e.g., Locke, 1976; Porter & Steers, 1973; Herzberg et al., Note 1) have documented the consistent and negative, although moderate, relationship between job satisfaction and turnover. Satisfaction is seen as the affective response to evaluation of the job. This evaluation is considered to be a function of perceptions of various aspects of the job relative to individual values (Locke, 1969, 1976). It is important to note that satisfaction is present rather than future oriented. The behavioral implication of satisfaction–dissatisfaction is a tendency toward approach–avoidance. However, whether this approach–avoidance tendency is expressed in the form of turnover is thought to be related to at least three other classes of variables: attraction expected utility of the present role, attraction expected utility of attainable alternative roles, and centrality of work values, beliefs regarding nonwork consequences of quitting–staying, and contractual constraints. Failure to consider these classes of variables may explain the absence of a stronger relationship between job satisfaction and turnover.

Attraction and Expected Utility of Present Job

Whereas satisfaction is present oriented, attraction is considered to be future oriented. Attraction is seen as being based on the expectancies that the job will lead to future attainment of various positively and negatively valued outcomes. When combined with the expectancy of being able to retain the present job, an index can be generated that is analogous to Vroom's (1964) *force* for a single alternative and the *expected utility* index of Dachler and Mobley (1973) or Graen (1976).

The concept of expected utility is applied in a variety of models. For example, economists and decision theorists frequently use *expected utility* and *expected value,* concepts analogous to the expected utility previously described (see March & Simon, 1958, pp. 137–138). In one interdisciplinary analysis, Blau, Gustad, Jessor, Parnes, and Wilcox (1956) conceptualized the evaluation of occupational alternatives as "the individual's valuation of the rewards offered by different alternatives and his appraisal of his chances of being able to realize each of the alternatives" (p. 533).

It is thought that attraction expected utility of the present role, like satisfaction, contributes to the tendency toward approach–avoidance. Although many studies have analyzed the satisfaction–turnover relationship, the dual contribution of satisfaction and attraction expected utility to turnover has not been researched. While there may be some correlation between satisfaction and attraction expected utility, these variables are conceptually distinct and should have separate effects on intentions (to search or to quit) and turnover. For example, individuals may be satisfied (or dissatisfied) with their present job, but may expect the present job to be relevant (or irrelevant) to their subsequent career. Graen and Ginsburgh (1977) found the latter belief to be significantly related to resignation. On the other hand, one may be dissatisfied with one's work group but be attracted to it because of expectations that it will facilitate the future attainment of valued outcomes or goals. The above relationships can easily be extended to include a variety of other job factors, for example, supervision, benefits, and so forth.

Just as there are multiple dimensions of satisfaction, there are multiple dimensions of attraction. The salience of these different dimensions is a function of individual differences in values. The values may be related to occupation, position level, age, tenure, and other personal variables.

One dimension of satisfaction and attraction concerns organizational goals and values. The congruence between individual and organizational goals and values has been defined by Porter et al. (1974) and Steers (1977) as one component of organizational commitment. As noted earlier, these authors also included willingness to exert effort, desire and intention to remain in the organization, and job satisfaction in the definition of commitment. The model suggested here seeks to subdivide the complex variable of commitment. Congruence between individual and organizational goals and values may be an important variable, but can be seen as distinct from, and only one of several focuses of, both satisfaction (present) and attraction (future), which are in turn related to turnover intentions and behavior.

If both satisfaction and attraction expected utility contribute to intentions to search and quit, and to turnover, then it is necessary to analyze the conditions under which one or the other makes the most contribution to variance explained. It may be that individual-level variables such as the need for immediate versus delayed gratification (see, e.g., Mischel, 1976) will aid in predicting whether satisfaction (present) or attraction (future) is most strongly related to turnover intentions and behavior for given individuals.

Attraction and Expected Utility of Alternatives

Considering both satisfaction and attraction expected utility should increase our understanding and prediction of turnover intentions and behavior. However, the attraction and attainability of alternative jobs or roles must also be considered. March and Simon (1958) presented an organizational participation model that gave a prominent role to visibility of alternatives. The March and Simon components of "perceived desirability of leaving the organization" and "perceived ease of movement from the organization" (p. 93) roughly correspond to "expectancies re: future job outcomes" and "expectancy re: attaining alternative" in Figure 1. As noted earlier, these variables have received little attention in turnover research.

The present model suggests that it is not merely the visibility of alternatives but the attraction of alternatives and the expectancy of attaining the alternatives that are most salient. Forrest et al. (1977), Mobley (1977), and Schneider (1976) are among recent authors who make a strong argument for inclusion of the variable *attraction of alternatives* in turnover research. Attraction of alternatives is defined in terms of expectations that the alternative will lead to the future attainment of various positively and negatively valued outcomes. When combined with the expectancy of being able to attain the alternative, an index can be generated that is analogous to Vroom's (1964) force for a single alternative and to the expected utility index of Dachler and Mobley (1973) or Graen (1976). (See Mobley, 1977, for a microanalytic treatment of the possible role of alternatives in search and turnover intentions and behavior.)

As noted in Figure 1, there may well be some covariation among satisfaction, attraction expected utility of the present job, and attraction expected utility of alternatives. This is to be expected, since values are common to all three and the presence or absence of attractive alternatives may result in the revaluation of one's satisfaction with or the attraction of the present role.

Moderating Variables

Although satisfaction, attraction expected utility of the present job, and attraction expected utility of alternatives are considered to be the primary determinants of turnover intentions and behavior, several other variables can be expected to moderate these relationships. To the extent that nonwork values and interests are not central to an individual's life values and interests (Dubin et al., 1975) and to the extent that an individual associates significant nonwork consequences with quitting (see, e.g., Newman, 1974), the relationships among satisfaction, attraction, and turnover intentions and behavior will be attenuated. Additionally, to the extent that an individual is bound by a contract, as for example in professional sports, the military, and certain professions,

the relationships will be attenuated during the term of the contract. Under such circumstances, it can be hypothesized that the individual who is dissatisfied, perceives little attraction in the present job, or perceives an attractive alternative may engage in other forms of avoidance and withdrawal behavior.

These suggested moderating influences, especially nonwork values and interests and nonwork consequences of turnover behavior, call attention to the need to look beyond the work setting for a complete understanding of the psychology of the turnover process.

Antecedents

The antecedents of satisfaction and attraction are considered to be organizational variables as perceived by the individual, economic variables related to availability of alternatives as perceived by the individual, and individual-level occupational and personal variables as they influence individual values, perceptions, and expectations. Although a detailed analysis of these antecedents is beyond the scope of this article, it is important to emphasize that the influence of various organizational, economic or labor market, occupational, and personal variables is through individual perceptions, expectations, and values.

Research Implications

The model described here indicates the need for multivariate research on the turnover process. As noted in the review section of this article, although the negative relationships between both age and tenure and turnover are well established, the amount of variance explained is low and the psychology of the relationships is not well understood. The model proposed here suggests that multivariate research that concurrently assesses values, job-related perceptions, external perceptions, and the previously mentioned moderating variables should facilitate an understanding of the relationship of age and tenure to turnover.

Similarly, multivariate research that concurrently assesses individual-level occupational and personal variables, job-related perceptions, external perceptions, individual values, and potential moderating variables provides a framework for integrating and understanding, at the individual level, the aggregate-level effects of various organizational and economic or labor market variables summarized by Price (1977).

Graen (1976), among others, noted that neither individuals nor organizations are fixed or static; neither is the economy or labor market. The clear implication is that understanding the turnover process will require longitudinal as well as multivariate research. Longitudinal research, not simply in terms of the collection of criterion data over time but also in terms of repeated measures of the independent variables, as recently exemplified by Graen and Ginsburgh (1977) and Porter et al. (1976), is needed.

Conclusions

In 1973 Porter and Steers observed that the then existing body of research left much to be understood about the psychology of the employee withdrawal process. Review of the subsequent research leads to a similar observation. The conceptual model suggested here calls attention to the possible main effects of satisfaction (present oriented), attraction expected utility of the current role (future oriented), and attraction expected utility of alternative roles. A number of moderating variables and constraints were suggested. The need for integrative, multivariate longitudinal research is evident if significant progress is to be made in understanding the psychology of the employee turnover process.

Associative and Nonassociative Theories of the UCS Preexposure Phenomenon: Implications for Pavlovian Conditioning

Alan Randich and Vincent M. LoLordo
Dalhousie University, Halifax, Canada

Excitatory Pavlovian conditioning of a discrete conditioned stimulus is attenuated by prior exposure to the unconditioned stimulus. The unconditioned stimulus preexposure phenomenon is observed in a variety of Pavlovian conditioning procedures as diverse as eyelid conditioning, the conditioned emotional response, and conditioned taste aversion learning. This article discusses the variables that affect the unconditioned stimulus preexposure phenomenon and uses this information in evaluating both associative and nonassociative accounts of the phenomenon. At least one associative account, based on context blocking, and at least one nonassociative account, based on central habituation of the emotional response to the unconditioned stimulus, remain viable.

The primary goals of research in Pavlovian conditioning are to determine the variables that influence the formation of conditioned responses and then to specify their mechanisms of action. A number of investigators are currently examining how one such variable, the organism's experience with the unconditioned stimulus, affects the course of conditioning. It has been shown in a variety of Pavlovian conditioning paradigms that exposure to the unconditioned stimulus (UCS) prior to the initiation of pairings of the conditioned stimulus (CS) and the UCS attenuates the formation of the excitatory conditioned response (CR). The UCS preexposure effect interests many investigators because of their conviction that a thorough analysis of this phenomenon will further our understanding of the necessary conditions for Pavlovian conditioning.

In general, the UCS preexposure effect has been viewed from two different perspectives, each of which bears on the possible mechanism(s) of Pavlovian conditioning. Associative accounts of the UCS preexposure effect argue that during the preexposure phase, an animal learns some relation between the occurrence of the UCS and other events that occur in the situation, such as the relation between the UCS and contextual stimuli. The learning that occurs in the preexposure phase somehow interferes with the formation of an association between a nominal CS and the UCS in the second phase of the experiment. For example, a context-blocking interpretation of the UCS preexposure phenomenon (e.g., Rescorla & Wagner, 1972) posits that some stimulus aspect (X) of the experimental situation acquires associative strength during preexposure to an aversive UCS. Conditioning of Stimulus X reduces the amount of associative strength that a nominal stimulus (A) can acquire during subsequent excitatory conditioning in that environment (i.e., pairings of AX with the UCS). As a result, the rate of acquisition of an excitatory CR to Stimulus A is attenuated. On the other hand, nonassociative accounts generally hold that preexposure to the UCS reduces the organism's reactivity to subsequent applications of that UCS. Such a reduction in reactivity may result from either central habituation or peripheral sensory adaptation of the re-

This research was supported by Grant A-9585 from the National Research Council of Canada. We wish to thank J. Willner and A. L. Riley for comments on an earlier version of the article and J. Lord for preparation of the manuscript.

sponse to the UCS. In any case, reduced reactivity to the UCS should result in attenuated excitatory conditioning to a CS paired with that UCS.

The present article reviews the effects of preconditioning exposure to the UCS on the acquisition of excitatory CRs and evaluates the various hypotheses that have been advanced to explain this phenomenon. This review focuses on Pavlovian conditioning using aversive UCSs, since most of the published experiments on this phenomenon have used such stimuli. Moreover, the review focuses only on what Domjan and Best (1977) referred to as the durable UCS preexposure effect, which occurs even when long delays intervene between UCS preexposure and conditioning. The recent demonstrations of a transient or proximal UCS preexposure effect, which occurs only when the UCS is preexposed a short time before the conditioning trial, are not discussed (cf. Domjan & Best, 1977; Terry, 1976; Wagner, 1976).

Preconditioning Exposure to the UCS

In a typical Pavlovian conditioning experiment, a neutral stimulus (CS) is presented prior to and terminates with the presentation of a UCS. After repeated pairings of the CS and UCS, the previously neutral stimulus comes to elicit a CR. In this section, studies that present the UCS prior to the initiation of CS–UCS pairings, or preexpose the UCS, are organized according to the nature of their experimental paradigm. The paradigms include human and rabbit eyelid conditioning procedures, conditioned emotional response (CER) procedures, and conditioned taste aversion procedures.

Human and Rabbit Eyelid Conditioning

Taylor (1956) preexposed each of three groups of human subjects to 50 presentations of an air puff UCS to the cornea of the eye. The intensity of the UCS was either 15 mm, 30 mm, or 80 mm. In each group the amplitude of the unconditioned eyeblink response (UCR) decreased significantly with repeated presentations of the UCS, but there were no significant between-groups differences in the amplitude of the UCR. Each subject then received 50 presentations of a 520-msec light paired with an air puff of 30 mm to the cornea. The number of eyeblink CRs was greatest in the group that received no preexposure to the UCS, whereas the number of CRs in the groups preexposed to the UCS was an inverse function of the intensity of the UCS used during the preexposure phase.

Taylor considered the possibility that groups preexposed to the air puff UCS showed a reduced number of eyeblink CRs during excitatory conditioning because of peripheral sensory adaptation of the UCR. However, she rejected peripheral sensory adaptation as a complete explanation of these effects because there was no evidence of differential UCR magnitudes in the three UCS intensity groups at any time during the preexposure phase. Such differences would be expected to accompany differential sensory adaptation.

As an alternative explanation, Taylor suggested that a more general emotional or fear response elicited by the UCS was reduced in magnitude as a result of preexposure to the UCS. This argument requires two assumptions. It assumes that acquisition of an excitatory CR depends in part on an association formed between the CS and the organism's emotional reaction to the UCS. Konorski (1967) made a similar, albeit more general, point, asserting that in all Pavlovian aversive conditioning, a fear (preparatory) response is first conditioned to the CS and that the presence of this preparatory CR is necessary for the formation of a consummatory CR, for example, the eyeblink response. Second, the argument assumes that preexposure to the UCS reduces the magnitude of this general emotional response elicited by the UCS, even though the specific UCR (in Konorski's terms, the consummatory response) measured by an experimenter may be relatively unaffected. The slower rates of acquisition of an excitatory CR in subjects preexposed to the UCS would then reflect a reduced emotional responsiveness relative to that of subjects not preexposed to the UCS.

Kimble and Dufort (1956) also examined the effect of preexposure to an air puff UCS on subsequent acquisition of the eyeblink response in humans. One group of subjects were preexposed to 20 air puffs (90 mm), while a second group of subjects received no preexposure treatment. Both groups then received 60 conditioning trials in which a .25-sec light CS was paired with an air puff UCS (90 mm). The group preexposed to the UCS acquired the eyeblink CR slower than the no-preexposure controls. These authors also offered an explanation based on motivational factors, but in one respect it is the opposite of the account suggested by Taylor. According to their view, preexposure to the UCS produces an increase in drive, and this drive energizes the subject's dominant habit regardless of its nature. If the subject's dominant habit before conditioning were not the CR and, indeed, if the dominant response to the CS were antagonistic to the CR, then increasing the subject's drive would interfere with subsequent excitatory conditioning.

In a similar experiment, Hobson (1968) preexposed college men and women rated as high- or low-anxiety subjects on the Taylor Manifest Anxiety Scale to air puffs (1.5 lb/sq. in.) delivered to the cornea of the eye for 0, 35, or 70 trials. Following preexposure to the UCS all subjects received excitatory conditioning of the eyelid response. The number of CRs obtained during excitatory conditioning was inversely related to the number of preexposures to the UCS. In addition, high-anxiety subjects acquired the CR significantly faster than low-anxiety subjects, although both classes of subjects showed a preexposure effect. If manifest anxiety is considered a source of drive, then Kimble and Dufort's account predicts less interference and hence faster eyelid conditioning in low-anxiety subjects than in high-anxiety subjects. On the other hand, perhaps Hobson's anxiety variable represents some aspect of general emotional responsiveness. Low-anxiety subjects preexposed to the UCS may acquire the excitatory CR at an even slower rate than high-anxiety subjects preexposed to the UCS because of a reduced emotional responsiveness to aversive stimuli.

Siegel and Domjan (1971) preexposed one group of rabbits to 550 100-msec, 200-V shocks to the infraorbital region of the eye, whereas a second group of rabbits received no preexposure to the UCS. Infraorbital shock elicits an unconditioned extension of the nictitating membrane, or third eyelid, in the rabbit. The nictitating membrane response was then conditioned in both groups by pairing a 500-msec tone with a UCS of the same intensity as that used during the preexposure phase. The rabbits preexposed to the UCS showed a slower rate of acquisition of the nictitating membrane CR than the no-preexposure controls.

In a more extensive study, Mis and Moore (1973) preexposed groups of rabbits to electric shock delivered to the infraorbital region of the eye and varied both the number of preexposed UCSs (0, 50, 200, or 350) and the interval between the last preexposed UCS and subsequent excitatory conditioning of the nictitating membrane response (30 sec vs. 24 hours). There were no significant changes in the amplitude of the UCR over trials during the preexposure phase. The rate of acquisition of the nictitating membrane response was reduced in both the 30-sec-delay and the 24-hour-delay groups, relative to controls that received no preexposure, and was an inverse function of the number of shocks administered during the preexposure phase. Moreover, rabbits in the 30-sec-delay groups acquired the excitatory CR at a slower rate than their counterparts in the 24-hour-delay groups. In general, there were no differences in the asymptotic levels of excitatory conditioning in the various groups after repeated CS–UCS pairings.

In a second experiment, groups of rabbits were preexposed to (a) no shocks, (b) 450 1-mA shocks, (c) 450 3-mA shocks, or (d) 450 5-mA shocks to the infraorbital region of the eye. There were no decrements in the amplitude of the UCR over successive preexposures to the UCS, and the UCRs to shocks of various intensities were comparable. All groups then received immediate excitatory conditioning of the nictitating membrane response; the CS was paired with the 3-mA UCS. The nictitating membrane CR

was acquired fastest in the no-shock and 1-mA groups, and slowest in the 3-mA and 5-mA groups. However, all groups eventually attained approximately the same asymptotic level of conditioning.

Mis and Moore's experiments show that the decremental effect of preexposure to the UCS on the rate of acquisition of the nictitating membrane response is a direct function of the number of preexposures to the UCS (cf. Hobson, 1968), a direct function of the intensity of the prior UCSs (cf. Taylor, 1956), and an inverse function of the time interval between the last preexposure to the UCS and the initiation of excitatory conditioning. Thus, analogous parametric manipulations during preexposure to the UCS, for example, variations of the number of preexposures, produce similar effects on conditioning of the eyelid response in humans and conditioning of the nictitating membrane response in rabbits.

It is unlikely that sensory adaptation to the UCS can account for the retarded acquisition of excitatory conditioning in Mis and Moore's experiments because the amplitude of the UCR did not change during preexposure to the UCS. Furthermore, different UCS intensities produced comparable UCRs, as was the case in Taylor's study of the human eyeblink.

Several investigators (e.g., Rudy, Iwens, & Best, 1977; Tomie, 1976) have asserted that the UCS preexposure effect can be explained in terms of blocking of conditioning to the nominal CS in the second phase of the experiment as a result of prior excitatory conditioning of some cues that were present in both phases (Kamin, 1969). In Kamin's original demonstration of blocking, one group of rats were exposed to repeated presentations of Stimulus A paired with electric shock in a CER paradigm (Estes & Skinner, 1941), whereas a second group of rats received no treatment. Then both groups received presentations of a compound stimulus (AB) paired with an electric shock of the same intensity as that used during the first phase of the experiment. Following the compound conditioning, the conditioned properties of A and B were assessed. The group that had received no treatment in the initial phase showed strong conditioned suppression during both Stimulus A and Stimulus B. The group that had received conditioning of Stimulus A in the initial phase showed strong conditioned suppression during test presentations of Stimulus A alone but little or no suppression during presentations of Stimulus B alone. Thus, prior conditioning of Stimulus A is said to block the conditioning of Stimulus B that normally occurs when the compound stimulus, AB, is paired with a UCS.

A blocking interpretation of Mis and Moore's UCS preexposure effect would hold that some static cues present in the experimental environment during the preexposure phase, call them contextual cues, acquire associative strength by virtue of their presence when the UCS occurs. Then when the excitatory conditioning phase begins, the nominal CS conveys less information about the UCS than in control groups because contextual cues already predict the occurrence of the UCS. Hence, acquisition of the excitatory CR is retarded.

Mis and Moore concluded that a blocking interpretation of their data is highly speculative because there is no independent evidence that the rabbit nictitating membrane response can be conditioned to background cues (cf. Plotkin & Oakley, 1975; Moore, Note 1). However, this would not preclude conditioning of some preparatory, emotional response to the background stimuli. Suppose that the nictitating membrane CR can only be evoked by CSs that already evoke an increase in a preparatory, emotional response. Then prior conditioning of the emotional response to contextual cues could block conditioning of the emotional response to the nominal CS in the second phase, thereby blocking conditioning of the nictitating membrane response. However, if one assumes that the background stimuli are much less salient stimuli than the nominal CS, then one should expect a relatively small blocking effect (Feldman, 1975; Hall, Mackintosh, Goodall, & dal Martello, 1977).

Mis and Moore's interpretation of their results was that preexposure to the UCS made the rabbits less emotionally reactive

to the UCS and that reduced responsiveness to the UCS slowed the rate of excitatory conditioning—an argument identical to that proposed by Taylor (1956).

Conditioned Emotional Response Paradigms

Kamin (1961) examined the effect of prior exposure to electric shock on the subsequent acquisition of a conditioned emotional response (CER). In Experiment 1, two groups of rats were trained to bar press for food reinforcement on a variable-interval (VI) schedule. One group of rats then received 10 days of exposure to a .5-sec, .8-mA electric shock delivered through a grid floor at the rate of four shocks per day. A second group of rats received no preexposure treatment, but both groups of rats continued bar pressing for food reinforcement during this period. All rats then received CER training in which pairings of a 3-min white noise CS and a .5-sec, .8-mA electric shock were superimposed on the VI baseline. The group preexposed to the UCS showed a retarded rate of acquisition of conditioned suppression relative to the no-treatment controls.

Kamin replicated these findings in a second experiment using a 1.0-mA electric shock in both the preexposure and the conditioning phases. However, he observed that the decremental effect of preexposure to the UCS was reduced relative to the first experiment. Further, Kamin commented that a group of rats preexposed to a .72-mA electric shock readily acquired the CER if the intensity of the UCS used in the excitatory conditioning phase was 2.4 mA.

In a third experiment, Kamin assessed the effect of UCS intensity. Essentially the same procedure was used as in Experiment 1, except that three groups of rats were preexposed to shock intensities of .28 mA, .49 mA, or .85 mA. All groups then received CER conditioning with a .85-mA UCS. Groups that were preexposed to the UCS showed a retarded rate of acquisition of the CER relative to no-preexposure controls, and the magnitude of the retardation effect was a direct function of the intensity of the UCS used during preexposure (cf. Mis & Moore, 1973; Taylor, 1956).

A final experiment was conducted to determine whether the delivery of shocks during the preexposure phase retarded the acquisition of a CER because of contiguous pairings of the bar-press response and the UCS. One group of rats were preexposed to shock with the bar present and the VI contingency in effect (on-baseline treatment), whereas a second group of rats were preexposed to shock with the bar absent and the VI contingency eliminated (off-baseline treatment). Both groups showed a slower rate of acquisition of the CER than did the no-preexposure controls, but the rats that received shocks in the off-baseline treatment acquired the CER faster than those that received the on-baseline treatment. Kamin reported that on- versus off-baseline preexposure treatments did not produce differences in the baseline rates of responding on the VI schedule during excitatory conditioning.

Kamin suggested that some central habituation of emotional reactivity to the UCS resulted from preexposure to the UCS and produced retarded acquisition of the CER. This account is similar to the general emotional reactivity account of the preexposure phenomenon suggested by Taylor and by Mis and Moore. Note that such an explanation can also account for the differences between the on- versus off-baseline preexposure effects. Suppose that central habituation of emotional reactivity is relatively specific to the situation in which shock is administered. Then one would expect more stimulus generalization decrement of habituation, and hence faster excitatory conditioning, when the stimulus conditions are different in the preexposure and conditioning phases.

Kamin's experiments extend the UCS preexposure phenomenon to a new species, rats, and to another widely studied Pavlovian conditioning paradigm, CER. Further, they suggest that the magnitude of the retardation of the acquisition of a CER is a direct function of the intensity of the UCS used during preexposure. However, Kamin included no group preexposed to a UCS intensity that exceeded the intensity used in the subse-

quent excitatory conditioning phase. Thus, it is possible that the decremental effect of preexposure to a UCS on the acquisition of a CER simply reflects similarities between the intensity of the preexposure UCS and the intensity of the UCS used during excitatory conditioning, rather than an effect of UCS intensity during preexposure per se. Such an account suggests that the magnitude of the UCS preexposure effect would also be diminished when the UCS is much more intense during preexposure than during excitatory conditioning. Indeed, Randich (1978) obtained this outcome using electric shock as a UCS and the CER as a measure of excitatory conditioning. Groups of rats were preexposed to 0-mA, .3-mA, .5-mA, .8-mA, or 1.3-mA unsignaled electric shocks for 10 days. All groups then received pairings of a 3-min white noise CS with a .8-mA electric shock. All groups preexposed to electric shock showed retarded acquisition of the CER relative to the no-preexposure control group (0 mA), but the greatest attenuation of CER acquisition occurred in the group both preexposed and conditioned with the .8-mA electric shock. The groups that received a shift in UCS intensity between the preexposure and CER conditioning phases acquired the CER faster than did the nonshifted group.

Thus, if groups of subjects are preexposed to a wide range of UCS intensities and all are conditioned at an intermediate UCS intensity, then the magnitude of the UCS preexposure effect is a direct function of the intensity of the preexposed UCS in both human eyelid (Taylor, 1956) and rabbit nictitating membrane (Mis & Moore, 1973) paradigms, but is an inverted-U-shaped function of the intensity of the preexposed UCS in the CER paradigm (Randich, 1978). The different functions yielded by different response systems have important implications for understanding the mechanism(s) of the UCS preexposure phenomenon.

For example, a context-blocking account of the UCS preexposure phenomenon, at least in the interpretation offered by the model of Rescorla and Wagner (1972), predicts that the magnitude of the UCS preexposure phenomenon should be an increasing function of the intensity of the UCS used during preexposure. However, such a view would have difficulty explaining the inverted-U function obtained by Randich, unless one assumes that shifts in UCS intensity between the preexposure and conditioning phases result in stimulus generalization decrement of the associative strength of contextual cues and thus in a decrease in context blocking. Granting that possibility, however, why would stimulus generalization decrement not occur in the eyelid and nictitating membrane procedures?

Brimer and Kamin (1963), Kremer (1971), and Baker (1974) have also reported similar attenuation of a CER following off-baseline preexposure to shocks. On the other hand, Mackintosh (1973) failed to observe a significant preexposure effect in a CER procedure, although preexposed rats on the average acquired the CER slower than no-preexposure controls (see also, Pearce & Dickinson, 1975, Experiment 1).

Rescorla (1973) preexposed one group of rats to 72 2-sec loud noise presentations (112 dB; SPL), whereas a second group of rats received no preexposure treatment. Both groups then received pairings of a 30-sec visual stimulus with the loud noise UCS in a CER procedure. The group preexposed to the loud noise UCS acquired conditioned suppression at the same rate as no-preexposure controls, that is, there was no preexposure effect on acquisition of the CER. However, during a 3-day extinction procedure, in which the CS was presented alone, the CER of the group preexposed to loud noise extinguished more rapidly than did the CER of the no-preexposure controls. It is difficult to explain the failure of this preexposure treatment to retard the formation of a CER. Further investigations of this discrepancy should focus on the distal nature of the UCS, the nature of the UCR to loud noise (cf. Bolles & Seelbach, 1964), and the parametric effects of intensity with a loud noise UCS.

In another experiment, Rescorla (1974) preexposed three groups of rats to a total of eight .5-sec shocks of .5-mA, 1.0-mA, or 3.0-

mA intensity. Each preexposed shock was preceded by a 2-min flashing light in an effort to prevent fear conditioning to contextual stimuli. Following a 72-hour delay in which the food-reinforced baseline response was reestablished, a 2-min tone CS was repeatedly paired with a .5-sec, .5-mA electric shock. Rescorla found that the rate at which the CER was acquired was a direct function of the intensity of the UCS used during the preexposure phase. However, a control group that received no preexposure treatment was not included in this experiment, making it impossible to determine whether the groups preexposed to a UCS showed an accelerated or retarded rate of acquisition of the CER.

Randich (1978) provided a more complete investigation of the effects of preexposure to a signaled UCS on acquisition of a CER by including a no-preexposure control group as well as a group preexposed to a weaker shock than the shock used during CER conditioning. Groups of rats were preexposed to a total of 30 .5-sec shocks of .5-mA, .8-mA, or 1.3-mA intensity, distributed over 10 days. Each preexposed shock was preceded by a 3-min light stimulus, and a no-preexposure control group (0 mA) received exposure to the light stimulus alone. All groups then received pairings of a 3-min white noise CS with the .8-mA electric shock. All groups preexposed to electric shock acquired the CER at a slower rate than the group preexposed to the light stimulus alone, and the greatest attenuation of CER conditioning occurred in the group both preexposed and conditioned with the .8-mA electric shock. This pattern of results includes a replication of those obtained by Rescorla (1974). Moreover, the pattern of results obtained with preexposure to signaled shocks duplicates the pattern of results obtained by Randich (1978) with preexposure to unsignaled shocks. Since one would assume that signaling the preexposed UCS would minimize conditioning of contextual cues, the similar pattern of results obtained with preexposure to signaled versus unsignaled electric shock suggests that, at a minimum, context blocking is not the only factor responsible for the UCS preexposure phenomenon with a CER procedure.

Conditioned Taste Aversion Paradigms Within UCS Comparisons

Elkins (1974) preexposed groups of rats to injections of the emetic cyclophosphamide (12.5 mg/kg) for 0, 1, 3, or 6 days over the course of a 2-week period. All subjects were then deprived of water. They were then presented with a .1% saccharin solution for a minimum of 10 minutes and for 5 minutes after the onset of drinking. Five minutes after the removal of saccharin, each group was injected with cyclophosphamide (12.5 mg/kg). On the day following the conditioning trial, and for 60 days thereafter, each subject was given free access to both saccharin solution and tap water presented in separate bottles, that is, extinction testing. In general, Elkins found the initial attenuation of the aversion to saccharin to be a direct function of the number of preexposures to cyclophosphamide injections. Moreover, the rate at which the aversion to saccharin extinguished over the 60-day period was a direct function of the number of preexposures to the UCS.

In a similar design, Vogel (Note 2) showed that preexposure to amobarbital attenuated the aversion induced by pairings of a novel taste with amobarbital as a direct function of the number of preexposed UCSs (0, 1, 3, or 5).

Cannon, Berman, Baker, and Atkinson (1975) preexposed three groups of rats to ethanol intubation (4 g/kg) for 1, 3, or 5 successive days, whereas two other groups of rats received intubation with equivalent volumes of water. All of the groups preexposed to ethanol and one group preexposed to water then received saccharin–ethanol (4 g/kg) pairings for 3 days, while the second group preexposed to water received saccharin–water pairings. Conditioning trials were spaced 3 days apart. None of the groups preexposed to ethanol showed an aversion to saccharin following the first pairing of saccharin and ethanol, that is, they drank as much saccharin solution as the group that received no preexposure treatment and a saccharin–water pairing. On the other hand, the control group given no preexposure followed by a pairing of saccharin and ethanol showed

a strong aversion to saccharin after a single conditioning trial. By the third conditioning trial, animals that had been preexposed to ethanol did show an aversion to saccharin, but it was attenuated relative to controls. The magnitude of the attenuation effect was a direct function of the number of preexposures to ethanol.

Elsmore (1972) preexposed groups of rats to delta-9-tetrahydrocannabinol (THC; 10 mg/kg) for 0, 1, 2, 4, or 8 days. All groups then received a single pairing of saccharin and delta-9-THC (10 mg/kg) followed by a two-bottle test in which they could drink either saccharin or water. All groups showed approximately the same aversion to saccharin, although there was a nonsignificant trend indicating that the aversion was weakest in the groups that received the greatest number of preexposures to delta-9-THC. It is important to note that a two-bottle test is a good method for detecting very weak aversions, but is less effective than a one-bottle test in demonstrating between-groups differences in the strength of an aversion when all groups have a moderate to strong aversion.

In summary, the data on the effect of the number of preexposures to the UCS on subsequent conditioning of a taste aversion generally complement the findings reported with human and rabbit eyelid conditioning (Hobson, 1968; Mis & Moore, 1973). The data of Cannon et al. (1975) also suggest that repeated conditioning trials may sometimes be required to reveal the effect of some parametric variation of a UCS preexposure treatment that is not detected following a single conditioning trial. Elsmore's (1972) failure to obtain a preexposure effect with delta-9-THC may reflect either the use of a single conditioning trial or, as noted above, the use of a two-bottle test.

The effect of variations in the interval between preexposure to a drug UCS and subsequent conditioning of an aversion to a taste paired with that drug has been investigated in several experiments by Cappell and LeBlanc. They showed that the magnitude of the attenuating effect of prior exposure to either D-amphetamine (Cappell & LeBlanc, 1975) or morphine (Cappell & LeBlanc, 1977) on subsequent taste aversion learning with the same UCS decreases as the time interval increases between the last preexposure to the UCS and the start of conditioning (cf. Mis & Moore, 1973). Moreover, the dissipation of the UCS preexposure effect with delays to the start of conditioning was more pronounced with amphetamine than with morphine.

Several studies have examined the effect of drug dosage during preexposure on the magnitude of the UCS preexposure effect. Cannon et al. (1975) preexposed groups of rats to a single saline injection or an injection of either .12-M or .36-M lithium chloride (LiCl; an emetic). Saccharin was then paired with injections of saline, .12-M LiCl, or .36-M LiCl in a factorial design. The decremental effect of preexposure to LiCl on subsequent taste aversion learning was a direct function of the preconditioning dosage of LiCl. The magnitude of the decremental effect of preexposure to a given dosage of LiCl was an inverse function of the conditioning dosage; that is, the greater the conditioning dosage, the greater the aversion, given a constant preconditioning dosage. Thus, there was no interaction between preconditioning dosage and conditioning dosage; these variables appear to combine in a simple linear fashion. The pattern of results obtained in this study is similar to that obtained in human eyeblink and rabbit nictitating membrane conditioning procedures but not in the CER procedure with rats.

Parker, Failor, and Weidman (1973) preexposed two groups of rats to chronic morphine treatment over a 25-day period, while a third group of rats received no preexposure treatment. The dosage of morphine was gradually increased over the preexposure period, and reached a final level of 140 mg/kg per day, a large dose. A preconditioning preference test between sucrose-octa-acetate (SOA) solution and water was then administered to all rats during a period in which the addicted rats were deprived of morphine for 96 hours. Subsequently, one group of rats that had been preexposed to morphine were repeatedly injected with morphine after consuming SOA; a second group of rats preexposed to morphine were injected with morphine after

no-liquid sessions; and a third group of rats that received no preexposure treatment were injected with morphine after consuming SOA. These injections were spaced 72 hours apart and thus occurred when the previously addicted rats were suffering withdrawal stress. The rats preexposed to morphine prior to pairings of SOA and morphine showed an attenuated aversion to SOA relative to the rats that received no preexposure treatment prior to SOA–morphine pairings. In addition, rats preexposed to morphine prior to SOA–morphine pairings showed a preference for SOA when compared with rats preexposed to morphine and then given morphine injections after no-liquid sessions. Perhaps even stronger testimony to the effect of chronic pretreatment with morphine on the impact of SOA paired with morphine is that seven rats that were not addicted to morphine but were conditioned with morphine died. No rats addicted to morphine and conditioned with morphine died.

The authors concluded that chronic preexposure to morphine creates an unnatural need state for the drug. By this view, SOA–morphine pairings do not induce an aversion in rats pretreated with morphine because SOA comes to signal alleviation of withdrawal symptoms induced by the need for morphine. Indeed, SOA that has been paired with morphine might even be expected to elicit a stronger approach response in rats pretreated with morphine than in appropriate controls.

LeBlanc and Cappell (1974) attempted to test the unnatural need state hypothesis in two experiments. In Experiment 1, chronic preexposure to either a large (200 mg/kg) or moderate (40 mg/kg) daily dose of morphine eliminated the formation of an aversion to saccharin induced by saccharin–morphine (20 mg/kg) pairings in the morning, and there was no evidence of any conditioning with repeated taste–drug pairings. However, this outcome may reflect more than a UCS preexposure effect because the groups that were preexposed to morphine received a supplemental dose of morphine each afternoon to maintain the normal daily level of morphine. For example, the group preexposed to 200 mg/kg of morphine per day and conditioned with 20 mg/kg of morphine per day received a supplement of 180 mg/kg of morphine in the afternoon, following a taste–drug pairing in the morning. The implications of providing supplemental doses of morphine are unclear because little is known about the effects of interpolated presentations of the UCS between conditioning trials. However, it is possible that since these supplemental doses of morphine constituted from 50%–90% of the animals' normal daily morphine intake, saccharin–morphine pairings signaled an event of little metabolic consequence in satisfying a need state for morphine. Alternatively, this procedure could be viewed within the context of contingency theory, according to which the administration of morphine in the afternoon degrades the positive contingency between saccharin and morphine. This should render the CS a less effective signal (cf. Rescorla, 1967), resulting in little conditioning.

In a second experiment, chronic preexposure to either a large (20 mg/kg) or small (4 mg/kg) daily dose of D-amphetamine attenuated an aversion induced by pairing saccharin with D-amphetamine (1 mg/kg). The magnitude of the decremental effect of preexposure to D-amphetamine on the aversion to saccharin was larger in the high-dependence group than in the low-dependence group (see also, Goudie, Thornton, & Wheeler, 1976).

LeBlanc and Cappell argued that since there is no convincing evidence for a need state artificially induced by D-amphetamine withdrawal, there is no need to postulate a need state to account for the drug preexposure effect, even for so-called drugs of abuse. Instead, LeBlanc and Cappell argued that drug tolerance, or a diminished responsiveness to repeated administration of a constant dose of a drug, develops to presentations of either morphine or D-amphetamine during the preexposure phase and retards the development of an aversion to a taste paired with those drugs.

Cannon, Baker, and Berman (1977) have obtained evidence that is compatible with the claim that tolerance for the effects of a

drug contributes to the drug UCS preexposure effect. Rats that were repeatedly preexposed to ethanol and then given six pairings of saccharin and ethanol showed no tendency to acquire a saccharin aversion, whereas nonpreexposed controls formed a strong aversion. On the day following the last conditioning trial, the rats were intubated with ethanol and 30 minutes later were placed on a rotarod (a test of balance). Saccharin consumption and time on the rotarod, that is, maintenance of balance, were significantly positively correlated, $r(15) = .54$, leading Cannon et al. to conclude that tolerance for the effects of ethanol contributed a drug-specific component to their UCS preexposure effect.

On the other hand, Vogel (Note 2) asserted that drug tolerance is not a necessary condition of the drug preexposure effect. One group of rats received daily injections of amobarbital (80 mg/kg) for 5 days, whereas a second group of rats received injections of the vehicle. Both groups then received sweetened milk paired with amobarbital (80 mg/kg). The rats preexposed to amobarbital showed an attenuated aversion to sweetened milk relative to the no-preexposure control group. Vogel suggested that drug tolerance cannot entirely explain these results because the duration of sleep in rats preexposed to amobarbital was not significantly reduced relative to that of rats preexposed to the vehicle. Reduced sleeping time is often used as a measure of tolerance for barbiturates. In addition, if the attenuated taste aversion in animals preexposed to amobarbital reflects drug tolerance alone, there should be a correlation between reduced sleeping times and weaker taste aversions. Vogel found that this correlation was only .41. Perhaps stronger testimony against a drug tolerance hypothesis is Vogel's demonstration that a single preexposure to amobarbital given 2 days prior to a taste–drug pairing attenuated the aversion. Vogel argued that a single preexposure to amobarbital is unlikely to produce drug tolerance, although he presented no independent evidence to show that drug tolerance did not occur.

The rats in Vogel's experiments were deprived of food and water prior to each amobarbital injection during both the preexposure phase and the conditioning phase. Vogel recognized the possibility that during preexposure an aversion may have been conditioned to drive cues associated with deprivation states and that this aversion may have blocked subsequent taste aversion learning. Vogel tested this possibility by preexposing a group of rats to a total of three amobarbital injections (120 mg/kg) while the animals were maintained on ad libitum food and water. When tested while food deprived, so that any previously conditioned drive cues were absent, these animals still showed an attenuated aversion relative to no-preexposure controls. This experiment shows that conditioning an aversion to a drive state (Peck & Ader, 1974) is not a necessary condition for obtaining the UCS preexposure effect (cf. Braveman, 1975; Elkins, 1974).

Several studies using the conditioned taste aversion (CTA) paradigm not only have obtained a preexposure effect but also have found no evidence of conditioning even with repeated taste–drug pairings (Berman & Cannon, 1974; Cappell & LeBlanc, 1977; LeBlanc & Cappell, 1974). Brookshire and Brackbill (1976), for example, preexposed one group of rats to apomorphine injections (15 mg/kg) for 10 consecutive days, whereas a second group of rats received saline injections. The group preexposed to apomorphine formed no aversion to saccharin paired with an injection of apomorphine (15 mg/kg), even after repeated taste–drug pairings. Similarly, Cappell and LeBlanc (1975) showed that rats that had received 20 prior exposures to D-amphetamine (7.5 mg/kg) subsequently failed to develop an aversion to saccharin that was repeatedly paired with D-amphetamine (1.0 mg/kg). On the other hand, one or five prior exposures to the drug retarded, but did not prevent, the acquisition of a taste aversion (cf. Goudie et al., 1976). These findings contrast with experiments on human and rabbit eyelid conditioning and the CER, in which repeated CS–UCS pairings administered after preexposure to the UCS eventually yield a level of conditioning approxi-

mately equal to that of no-preexposure controls (Hobson, 1968; Kamin, 1961; Mis & Moore, 1973).

Riley, Jacobs, and LoLordo (1976) suggested that failures to obtain any conditioning with repeated taste–drug pairings following preexposure to the UCS may be restricted to addictive drugs (e.g., apomorphine, ethanol, and morphine) or to those drugs that animals will self-administer (e.g., amphetamine). They demonstrated that preexposure to six injections of LiCl (.15 M) attenuated an aversion established by a few pairings of saccharin and LiCl (.15 M), relative to no-preexposure controls. However, repeated saccharin–LiCl pairings eventually produced a substantial aversion to saccharin even in rats preexposed to LiCl. In a similar experiment, Cannon et al. (1975) preexposed groups of rats to a single LiCl intubation (.12 M) 1, 4, or 8 days prior to seven conditioning trials in which saccharin was paired with LiCl (.12 M). A single dose of LiCl given 1 day, but not 4 or 8 days, prior to conditioning attenuated the aversion to saccharin established by a single taste–drug pairing (cf. Cappell & LeBlanc, 1975, 1977). However, repeated taste–drug pairings induced a substantial aversion to saccharin even in the group given exposure to LiCl 1 day prior to conditioning.

Holman (1976) preexposed groups of rats to eight injections of either LiCl (.15 M) or saline and then conditioned an aversion by pairing the taste of sodium chloride (NaCl) with LiCl (.15 M). The group preexposed to LiCl showed a retarded acquisition of the aversion to NaCl, but substantial conditioning occurred with repeated taste–drug pairings.

Thus, the results of experiments with LiCl, a nonaddictive drug that animals will not self-administer, lend some support to the contention of Riley et al. that failures to obtain conditioning with repeated pairings of tastes and amphetamine, morphine, apomorphine, or ethanol following preexposure to these drugs reflect their addictive qualities, or animals' tendency to self-administer them. It is unfortunate, however, that none of the above experiments performed a direct comparison between addictive and nonaddictive drugs.

Several experiments have evaluated the effect of preexposure to signaled versus unsignaled drug UCSs on the subsequent formation of a taste aversion based on these drug UCSs. Cannon et al. (1975) showed that a single, signaled preexposure to LiCl does retard the acquisition of an aversion, although the decremental effect is smaller than that produced by a single, unsignaled preexposure to LiCl. In this experiment, one group of rats received a single sustacal–LiCl (.12 M) pairing, a second group of rats received a water–LiCl (.12 M) pairing, and a third group of rats received a sustacal–saline pairing. All groups then received a saccharin–LiCl (.12 M) pairing on the following day and on 3 additional days. Signaled and unsignaled preexposure to LiCl equally attenuated the aversion induced by saccharin–LiCl pairings on the first conditioning trial. However, repeated saccharin–LiCl pairings produced a stronger aversion in the signaled preexposure group than in the unsignaled preexposure group.

Mikulka, Leard, and Klein (1977) found an even more striking difference between the effects of signaled and unsignaled preexposure conditions. They observed that unsignaled preexposure to LiCl retarded subsequent conditioning even when signaled preexposure had no such effect. Saline-preexposed controls and a group that received four prior pairings of sucrose and LiCl acquired an aversion to almond-flavored water paired with LiCl equally rapidly, whereas a group that received four unsignaled exposures to LiCl showed a somewhat attenuated aversion to almond-flavored water.

Not all studies have obtained differences between signaled and unsignaled preexposure conditions. Goudie, Thornton, and Marsh (Note 3) found that unsignaled preexposure to methamphetamine and preexposures signaled by access to a saline solution had equal attenuating effects on subsequent conditioning of an aversion to saccharin paired with methamphetamine. Zellner and Riley (Note 4) obtained similar results with the stimulant drug methylphenidate. Goudie et al.'s failure

to obtain a difference between signaled and unsignaled preexposure conditions led them to consider the importance of the relationship between responding and the UCS during the preexposure phase. They suggested that during the preexposure phase, rats learn that the occurrence of the UCS is independent of their behavior. This learning, called "learned helplessness" by Maier and Seligman (1976), interferes with subsequent learning to withhold drinking in the presence of a taste cue that reliably precedes some UCS. Goudie et al. tested this notion by allowing groups of rats ad libitum access to only water or only methamphetamine during the preexposure phase. When rats were given some control over the preexposed UCS, that is, when the presentation of the UCS depended on responding, the attenuating effect of preexposure to the UCS was abolished (cf. Deutsch & Eisner, 1977). Recently, however, Randich (1978) reported that rats permitted to escape electric shock presentation during a preexposure phase and thereby to control the UCS showed attenuation of subsequent CER conditioning, even greater attenuation than yoked controls that could not escape electric shock during the preexposure phase.

Rudy, Iwens, and Best (1977) performed a series of experiments that showed that pairing a novel, exteroceptive background stimulus with poison during preexposure attenuates the development of a CTA regardless of whether the background stimulus is present or absent when excitatory conditioning is performed.

In Experiment 1, three groups of rats were preexposed to injections of LiCl (.15 M) for 4 days. Two of these groups received LiCl injections in the presence of a novel exteroceptive stimulus (a black chamber). The rat was first placed in the black chamber for 5 minutes, was then removed and injected with LiCl, and was finally replaced in the black chamber for an additional 25 minutes. A third group of rats received LiCl injections in their home cages. A fourth group of rats were simply placed in the black chamber and not injected with LiCl. Following the preexposure phase, one of the groups preexposed to poison in the black chamber received a single pairing of a saccharin infusion and a LiCl injection in the home cage. The other three groups received a single pairing of a saccharin infusion and a LiCl injection in the black chamber and were then removed to the home cage. A two-bottle test between saccharin and water in the home cage revealed that animals preexposed to LiCl in the home cage and conditioned in the black chamber did not significantly differ from the group that received no preexposure treatment; that is, the normal UCS preexposure effect was not obtained. However, preexposure to poison in the black chamber did attenuate the aversion to saccharin whether the saccharin–LiCl pairing occurred in the home cage or in the black chamber.

In a second experiment, Rudy, Iwens, and Best ruled out the possibility that the group preexposed to LiCl in the home cage and conditioned in the black chamber failed to show a preexposure effect because the novel stimulation produced by placement in the black chamber during conditioning in some way potentiated the effect of LiCl.

A third experiment showed that the 5-minute preinjection placement, rather than the 25-minute postinjection placement, in the black chamber during preexposure was responsible for the attenuation effect obtained in Experiments 1 and 2.

In a final experiment, two groups of rats received the preexposure to LiCl in the presence of either the novel black chamber or a novel light stimulus. A third group of rats received the preexposure treatment with LiCl in the presence of the black chamber after being familiarized with the black chamber by four prior placements in it. A fourth group of rats received LiCl injections in the home cage. All groups then received a single saccharin infusion paired with LiCl in the home cage. The results indicated that only the groups preexposed to LiCl in the presence of the unfamiliar, novel stimuli, that is, the black chamber or the light stimulus, showed the attenuation effect.

Rudy, Iwens, and Best found that rats preexposed to LiCl in the presence of a novel exteroceptive stimulus subsequently displayed

an attenuated taste aversion relative either to rats that received no prexposure treatment or to rats preexposed to LiCl in a familiar environment. They concluded that this attenuation effect was not a result of blocking by prior conditioning of the novel exteroceptive stimulus during preexposure to LiCl, because the attenuation occurred in groups preexposed to LiCl in the presence of a novel stimulus whether that stimulus was present or absent during subsequent conditioning of the aversion. If the novel exteroceptive stimulation was not present during saccharin–LiCl pairings, it could not have blocked conditioning to saccharin.

Instead, Rudy, Iwens, and Best (1977) argued that the handling and infusion procedure acquired associative strength during preexposure to LiCl and attenuated subsequent taste aversion learning. This explanation demands that the groups preexposed to LiCl in the presence of the novel exteroceptive stimulus more strongly associated the handling cues with poison than the groups preexposed to LiCl in the home cages, which were handled in the same way. For this to occur, Rudy, Iwens, and Best first assumed that handling cues were latently inhibited for all groups during the initial stages of the experiment, that repeated occurrence of the handling and infusion procedure prior to the preexposure phase rendered these cues less associable with UCSs. Placement in the novel chamber disrupted the latent inhibition such that the handling cues that would not otherwise have been associated with poison did acquire the associative strength necessary to attenuate the formation of a taste aversion.

In another series of experiments, Rudy, Rosenberg, and Sandell (1977) obtained evidence that supports this sort of account. Presentation of a novel exteroceptive cue just prior to the pairing of a familiar taste with LiCl injection enhanced the conditioning of aversion to the taste, an outcome formally similar to that postulated by Rudy, Iwens, and Best for familiar handling (rather than taste) cues.

Cross-UCS Comparisons

Gamzu (Note 5) preexposed two groups of rats to either D-amphetamine (2 mg/kg) or chlordiazepoxide (15 mg/kg) and two groups of rats to saline. The two drug-preexposed groups and one saline-preexposed group then received pairings of saccharin and D-amphetamine, while the other saline-preexposed group received pairings of saccharin and saline. The group preexposed to D-amphetamine showed an attenuated aversion to saccharin when compared with the group preexposed to saline and conditioned with D-amphetamine. However, the group preexposed to chlordiazepoxide and conditioned with D-amphetamine showed an aversion comparable with that of the no-preexposure controls. Thus, preexposure to D-amphetamine attenuates a conditioned aversion when this drug is used as the UCS, but preexposure to chlordiazepoxide does not affect the aversion induced by D-amphetamine.

Goudie and Thornton (1975) preexposed two groups of rats to either D-amphetamine (2 mg/kg) or *dl*-fenfluramine (6 mg/kg) for 9 consecutive days. Five days elapsed between the last UCS preexposure and the start of excitatory conditioning. During conditioning, half the rats in each group received pairings of saccharin and D-amphetamine, and the other half received pairings of saccharin and *dl*-fenfluramine. Preexposure to D-amphetamine attenuated the aversion induced by pairings of saccharin and D-amphetamine relative to the appropriate controls, but did not attenuate the aversion induced by pairings of saccharin and *dl*-fenfluramine. However, preexposure to *dl*-fenfluramine attenuated the aversion induced by either pairings of saccharin and *dl*-fenfluramine or pairings of saccharin and D-amphetamine.

Vogel (Note 2) preexposed groups of rats to either D-amphetamine (2 mg/kg), amobarbital (120 mg/kg), or the vehicle for 3 days. Then all groups were given taste–drug pairings in a factorial design. Preliminary work indicated that these dosages of D-amphetamine and amobarbital produced comparable aversions. Vogel found that preexposure to D-amphetamine did not attenuate

the aversion induced by pairing a taste and D-amphetamine, a result that runs counter to the results of Gamzu (Note 5) and Goudie and Thornton (1975). However, preexposure to D-amphetamine did attenuate the aversion induced by taste–amobarbital pairings. Furthermore, preexposure to amobarbital attenuated the aversion induced by taste–amobarbital pairings, but did not attenuate the aversion induced by taste–D-amphetamine pairings.

Cappell, LeBlanc, and Herling (1975) showed that chronic preexposure to D-amphetamine (20 mg/kg) administered over a 20-day period attenuated the aversion induced by pairing saccharin and morphine (6 mg/kg). Further, there was no evidence of conditioning even with repeated taste–drug pairings. However, preexposure to morphine facilitated an aversion induced by pairing saccharin and D-amphetamine (1 mg/kg). In a third experiment, chronic preexposure to chlordiazepoxide (25 mg/kg) for 22 days had no effect on the aversion induced either by pairing saccharin and D-amphetamine (1 mg/kg), a result consistent with that reported by Gamzu (Note 5), or by pairing saccharin and morphine (6 mg/kg). However, pretreatment with chlordiazepoxide did attenuate an aversion induced by pairing saccharin and chlordiazepoxide (cf. Gamzu, 1977).

Whaley, Scarborough, and Reichard (1966) preexposed two groups of rats to 1,000 rotations in a tumbling apparatus, whereas two other groups of rats were simply placed in the tumbling apparatus without being rotated. Twenty-four hours later, half the rats in each of these groups were irradiated with X rays (6 r./min.) for 10 minutes, while the other half in each group were sham irradiated. Immediately following this treatment, all rats received free access to tap water and saccharin for 20 minutes, so that saccharin consumption preceded some of the delayed effects of x-irradiation for rats in the experimental groups. A subsequent test found that the experimental group that had been tumbled showed an attenuated saccharin aversion relative to the irradiated group that had not been tumbled.

Braveman (1975) examined cross-UCS effects by preexposing groups of rats to injections of scopolamine methyl nitrate (1 mg/kg) for 0, 1, 3, 5, or 7 days and then giving them a single pairing of saccharin and LiCl (.3 M). Groups that were preexposed to scopolamine five or seven times consumed reliably more saccharin than the no-preexposure control group in a test following the saccharin–LiCl pairing. The amount of saccharin consumed in the test was a direct function of the number of preexposures to scopolamine. In a later study, Braveman (1977) also observed that preexposure to LiCl attenuated the magnitude of an aversion to a taste paired with scopolamine methyl nitrate.

Braveman (1975) considered the possibility that these drugs acted on the same physiological substrate and did not truly represent a cross-UCS effect. He attempted to eliminate this possibility by preexposing rats to either D-amphetamine (2 mg/kg) or scopolamine methyl nitrate (1 mg/kg), two drugs that induce conditioned taste aversions via different physiological substrates according to the ablation data of Berger, Wise, and Stein (1973). Rats that were preexposed to D-amphetamine then received a pairing of saccharin and scopolamine methyl nitrate, whereas rats that were preexposed to scopolamine methyl nitrate received a pairing of saccharin and D-amphetamine. In general, groups that were preexposed to a drug showed attenuated saccharin aversions relative to nonpreexposed controls. On the basis of this cross-UCS effect, Braveman concluded that drug preexposure did not modify the physiological mechanism that underlies conditioned food aversions.

Braveman also considered the possibility that cross-drug tolerance effects produced these results. He sought to eliminate this possibility by using mechanical rotation, rather than a drug, as a UCS. Groups of rats were either preexposed to rotation at 60 rpm for 15 minutes/day or injected with (a) scopolamine methyl nitrate, (b) D-amphetamine, or (c) LiCl for 5 days. All groups then received repeated pairings of saccharin and mechanical rotation. All of the groups preexposed to a UCS failed to show any aversion to saccharin, that is, they drank as much as controls that received neither preexposure nor

conditioning with the UCS. In a later study using a factorial design, Braveman (1977) preexposed rats to either LiCl injections or a severe electric shock treatment and a week later presented them with a taste followed by either LiCl or electric shock. A symmetrical cross-UCS preexposure effect was obtained. Braveman concluded that preexposure to any aversive UCS results in diminution of a general stress response to aversive stimuli, thereby reducing their impact during subsequent conditioning. Braveman's hypothesis is very similar to the emotional reactivity explanation of the preexposure effect suggested by other investigators (Kamin, 1961; Mis & Moore, 1973; Taylor, 1956).

Cannon et al. (1977) repeatedly preexposed rats to LiCl, ethanol, or NaCl and then presented half the rats in each group with pairings of saccharin and LiCl, whereas the others received saccharin followed by ethanol. Relative to saline-preexposed controls, rats that had been preexposed to one drug and then conditioned with another showed a strong UCS preexposure effect. However, the cross-UCS preexposure effect was significantly smaller than the within-UCS effect, leading Cannon et al. to conclude that in addition to some general mechanism that mediates cross-UCS preexposure effects, drug-specific components also contribute to the effect when the same drug is used during both preexposure and conditioning. As noted earlier, Cannon et al. suggested that tolerance contributed to the drug-specific effect, at least in the case of ethanol.

Summary of Studies Assessing Preconditioning Exposure to a UCS

The results of studies assessing the effect of preconditioning exposure to the UCS on human and rabbit eyelid conditioning, CER conditioning, and conditioning of taste aversions are briefly summarized below. The decremental effect of preconditioning exposure to the UCS on the formation of an excitatory CR is

1. In the human eyeblink, rabbit nictitating membrane, and taste aversion procedures a direct function of the intensity or concentration of an unsignaled preexposed UCS (Cannon et al., 1975; Mis & Moore, 1973; Taylor, 1956) and an inverse function of the intensity or concentration of the UCS used in excitatory conditioning (Cannon et al., 1975).
2. In the CER procedure, an inverted-U-shaped function of the intensity of an unsignaled (or signaled) preexposed UCS (Randich, 1978).
3. A direct function of the number of preexposed UCSs (Cannon et al., 1975; Elkins, 1974; Goudie et al., 1976; Hobson, 1968; Mis & Moore, 1973; Randich, 1978; Vogel, Note 2), even when cross-UCS comparisons are made (Braverman, 1975).
4. An inverse function of the time interval between the last preexposure to a UCS and the start of excitatory conditioning (Cannon et al., 1975; Cappell & LeBlanc, 1975, 1977; Mikulka et al., 1977; Mis & Moore, 1973).
5. Sometimes reduced if the preexposed UCS is signaled (Cannon et al., 1975; Mikulka et al., 1977; see also, Revusky, Parker, Coombes, & Coombes, 1976), although Goudie et al. (Note 3) and Zellner and Riley (Note 4) found no differences between signaled and unsignaled preexposure to the UCS on subsequent taste aversion learning (cf. Randich, 1978).
6. Not overcome by repeated CS–UCS pairings when some addictive drugs and amphetamine are used (Berman & Cannon, 1974; Brookshire & Brackbill, 1976; Cappell & LeBlanc, 1977; Cappell et al., 1975; LeBlanc & Cappell, 1974), but is overcome when nonaddictive drugs are used (Cannon et al., 1975; Holman, 1976; Riley et al., 1976).
7. Often independent of the type of aversive UCS used in the preexposure and conditioning phases (Braveman, 1975, 1977; Cappell et al., 1975; Goudie & Thornton, 1975; Whaley et al., 1966; Vogel, Note 2; Gamzu, Note 5).

Theoretical Considerations

In general, the studies examined in this article show that preconditioning exposure to aversive UCSs retards the formation of an excitatory CR. Further, this effect often occurs when the UCS used during the pre-

exposure phase is different from the UCS used during excitatory conditioning (cf. Braveman, 1975). The basis of this phenomenon remains an enigma, although both associative and nonassociative theories have been advanced. Many of these theories are of limited scope and confine their predictive value to particular situations, for example, those in which the UCS is an addictive drug (cf. Parker et al., 1973). This is not to say that such theories are incorrect; rather, the generality of the preexposure phenomenon across Pavlovian conditioning paradigms, species, and aversive UCSs invites a more general interpretation. It is toward this end that theories of the UCS preexposure effect are evaluated in the following sections.

Associative Theories

Blocking. As was noted earlier, a blocking interpretation of the UCS preexposure phenomenon posits that some stimulus aspect (X) of the experimental situation acquires associative strength during preexposure to an aversive UCS. Conditioning of Stimulus X reduces the amount of associative strength that a nominal stimulus (A) can acquire during subsequent excitatory conditioning in that same environment (AX). As a result, the rate of acquisition of an excitatory CR to Stimulus A is attenuated.

There are three critical assumptions of a blocking interpretation of the UCS preexposure effect. First, Stimulus X can be any aspect of the experimental situation. For instance, Stimulus X may be static cues provided by the characteristics of the experimental environment, cues provided by the handling procedure, or cues provided by the injection procedure in CTA experiments. Second, Stimulus X must be present during both the preexposure and the excitatory conditioning phases of an experiment for blocking to occur. Third, the presence of the previously conditioned Stimulus X interferes with conditioning of Stimulus A because the UCS can support only a limited amount of associative strength (Rescorla & Wagner, 1972) or because there is little conditioning to redundant predictors of reinforcement (Mackintosh, 1975). There are several predictions that can be derived from a blocking account of the UCS preexposure phenomenon:

1. Blocking predicts retarded acquisition of an excitatory CR to Stimulus A if conditioning of Stimulus X occurs during preexposure to the UCS and Stimulus X is present during excitatory conditioning of Stimulus A. Virtually all the studies evaluated in this article obtained an attenuation of excitatory conditioning following prior exposure to the UCS. These studies typically included some stimulus (X) during both the preexposure and the conditioning phases. This stimulus could block conditioning of Stimulus A. The questions at hand are whether such stimuli (X) are in fact conditionable and whether such conditioning is capable of blocking conditioning of a discrete Stimulus A.

Many of the aforementioned stimuli that can be identified as Stimulus X are conditionable. Tomie (1976) demonstrated that prior presentations of free food attenuate the rate of acquisition of an autoshaped keypeck response. Tomie's data suggest that conditioning of contextual stimuli during free-food presentations blocks conditioning of a nominal CS subsequently presented in the same context. Similarly, Willner (1978) demonstrated that rats preexposed to injections of LiCl in a distinctive environment develop a place aversion and that this conditioning attenuates the formation of an aversion to saccharin that is later paired with LiCl in the same place. In two separate experiments using D-amphetamine and LiCl as UCSs, Braveman (Note 6) preexposed and conditioned rats in either the same or different environments; the environments were distinguished by the level of auditory–visual stimulation. Braveman obtained a UCS preexposure effect only when preexposure and conditioning occurred in the same environment, supporting an associative explanation of the phenomenon.

However, it is not clear whether conditioning of contextual cues occurs in other preparations, such as in human and rabbit eyelid conditioning. Mis and Moore (1973) argued against a context-blocking interpre-

tation of their rabbit eyelid conditioning study, citing the lack of evidence that the nictitating membrane response in rabbits can be conditioned to contextual stimuli. Their claim may not bear directly on a general blocking view of the UCS preexposure phenomenon. Preexposure to a UCS may neither alter the specific UCR that an experimenter measures nor condition that UCR to contextual cues, but may instead condition a fear response elicited by the UCS to contextual cues. If this fear response is important for excitatory conditioning of the nictitating membrane response (cf. Konorski, 1967), then a blocking interpretation may still be useful. In fact, Hinson and Siegel (Note 7) have recently presented evidence in support of a context-blocking interpretation of the UCS preexposure effect in nictitating membrane conditioning.

Researchers have attempted to reduce the likelihood of context blocking by providing a nominal signal (CS) for the UCS during the preexposure phase. Insofar as conditioning occurs to the salient, nominal CS it will not occur to less salient contextual cues (cf. Kamin, 1969). Hence, no blocking should occur when a novel CS is subsequently paired with the UCS in the same context. Cannon et al. (1975) and Mikulka et al. (1977) showed that signaled preexposure either attenuates or eliminates completely the retardation of excitatory conditioning that is typically obtained with unsignaled preexposure conditions. These results are compatible with a blocking interpretation because contextual stimuli should acquire little or no associative strength during preexposure to signaled UCSs. However, Goudie et al. (Note 3) and Zellner and Riley (Note 4) reported that rats given signaled or unsignaled preexposure to stimulants showed equal attenuation of the acquisition of a taste aversion, relative to controls. Randich (1978) also reported that rats given signaled preexposure to an electric shock UCS showed greatly retarded acquisition of a CER, relative to appropriate controls.

A second source of stimulation that could potentially block conditioning of a nominal CS is the handling procedure. Rudy, Iwens, and Best (1977) specifically attempted to condition contextual cues by preexposing their rats to illness in the presence of a novel, exteroceptive stimulus, namely, a black chamber. This preexposure treatment attenuated the formation of a CTA to a greater extent than did preexposure to illness in the home cage. However, the effect of preexposure to the UCS in a novel environment occurred regardless of whether the novel exteroceptive stimulus was present or absent when taste–drug pairings were administered. This result seems incompatible with a blocking interpretation, which asserts that Stimulus X must be present during excitatory conditioning to block acquisition of conditioning to Stimulus A. Rudy, Iwens, and Best performed subsequent experiments that forced them to conclude that blocking was indeed responsible for their results, although not as a result of associative strength acquired by the novel, exteroceptive stimulus. They argued that the novel exteroceptive stimulus acted only as a disinhibitor of other latently inhibited background cues (the handling cues in particular), thus allowing these cues to acquire associative strength. Since the handling cues were present during pairings of Stimulus A with the UCS, they blocked conditioning of an aversion to Stimulus A.

Braveman (1978) reasoned that if conditioning to handling cues during drug preexposure were responsible for the UCS preexposure effect, then manipulations that should attenuate conditioning to handling cues should also attenuate the UCS preexposure effect. He varied the amount of handling received by groups of rats prior to preexposure to LiCl and found no evidence that this variable influenced the UCS preexposure effect, which was strong even in rats that had been handled for 21 days prior to preexposure. However, Braveman did not administer any saline injections prior to drug preexposure, leaving open the possibility that conditioning to injection cues was responsible for the UCS preexposure effect. Recent evidence (Willner, 1978; Poulos & Cappell, Note 8) indicates that cues associated with the injection of a drug can acquire associative strength and are capable of blocking

conditioning of an aversion to a distinctive taste. This conclusion is based on the finding that the normal UCS preexposure effect obtained by prior injections of a drug can be reduced by degrading the correlation between injection cues and the drug during the preexposure phase.

2. Blocking predicts that the effect of preexposure to the UCS should dissipate with the time to the start of excitatory conditioning, as long as the animal is maintained in the presence of Stimulus X during this period. This prediction is based on the view that the conditioned response to Stimulus X will extinguish during a delay period in which it is not reinforced. If the CR to Stimulus X is near zero at the start of excitatory conditioning, then blocking should not occur.

Mis and Moore (1973), Cappell and LeBlanc (1975, 1977), and Cannon et al. (1975) have shown that the magnitude of the UCS preexposure effect decreases as the time interval increases between the last preexposure to a UCS and the start of excitatory conditioning. In the CTA studies, the animals spent the delay period in the preexposure environment, that is, in the presence of Stimulus X. It is unclear whether this outcome reflects extinction of Stimulus X or some effect that is independent of context, since the experiments included no conditions in which the animals spent the delay interval in the absence of Stimulus X. A critical test of this prediction would involve removing half the preexposed animals from the preexposure environment. The group removed from the preexposure environment during the delay period should show a greater attenuation of excitatory conditioning than the group maintained in the preexposure environment.

In a procedure that is formally similar to that just described, Batson and Best (Note 9) preexposed rats to injections of LiCl after they were placed in a distinctive black box. Then over the next 8 days, half the preexposed rats received 16 trials in which they were placed in the black box and then injected with physiological saline. These trials should have extinguished any conditioned response to the black box and associated cues. The other rats remained in their home cages during this period. Then both groups received a single saccharin–LiCl pairing following placement in the black box. Finally, both groups and the nonpreexposed controls were permitted to drink saccharin in the home cage. Rats that had received extinction trials were as averse to saccharin as were nonpreexposed controls, but rats that had spent the interval between preexposure and conditioning in the home cage showed a strong UCS preexposure effect. Batson and Best concluded that associative blocking formed the basis of their UCS preexposure effect (cf. Hinson & Siegel, Note 7, for a similar manipulation and outcome).

3. Blocking predicts that an animal preexposed to the UCS should eventually attain the same level of excitatory conditioning as an animal not preexposed to the UCS, although this level of conditioning should be attained at a slower rate. This should occur because the UCS is presented only in the presence of the nominal CS during excitatory conditioning and never in its absence. According to the Rescorla–Wagner (1972) model, this should result in more nonreinforced than reinforced presentations of Stimulus X, and the associative strength of Stimulus X should decline to zero. The nominal Stimulus A will acquire as much associative strength as Stimulus X loses. Thus, for an animal preexposed to the UCS, Stimulus A is permitted to acquire as much associative strength as the Stimulus A for an animal not preexposed to the UCS. Mackintosh's (1975) model makes the same prediction, asserting that Stimulus X should lose associative strength because it is a poorer predictor of the UCS than is Stimulus A. Thus, the salience of Stimulus A will increase, and Stimulus A will gain associative strength. Preexposed and control groups have attained the same level of conditioning in several studies that continued to present CS–UCS pairings during excitatory conditioning (Holman, 1976; Kremer, 1971; Mis & Moore, 1973). However, a few studies failed to obtain any conditioning following preexposure to a drug, even with repeated CS–UCS pairings (Berman & Cannon, 1974; Braveman, 1975; Brookshire & Brackbill, 1976; Cap-

pell & LeBlanc, 1977; Cappell et al., 1975). These are notable exceptions, however, because all but Braveman's study involved the use of UCSs that an animal will self-administer, namely, D-amphetamine, morphine, and ethanol.

UCS controllability. Vogel (Note 2) and Goudie et al. (Note 3) proposed that an organism that is preexposed to an aversive UCS learns that the aversive state is uncontrollable. This learning produces an associative deficit that transfers to the excitatory conditioning phase and interferes with the learning of the relationship between the CS and the UCS. This hypothesis is an extension of the learned helplessness notion (Maier & Seligman, 1976), which essentially argues that the organism perceives the occurrence of the UCS during the preexposure phase as uncorrelated with anything it does or attempts to do. Thus, it is possible that the associative deficit produced by learning that either stimuli or responses are ineffective in predicting or controlling the UCS interferes with the formation of an association between the stimulus and the reinforcer during excitatory conditioning.

Data showing that signaled preexposure to a UCS reduces the preexposure effect (Cannon et al., 1975) could be interpreted to support this contention. This, of course, assumes that an organism can learn some form of preparatory response during signaled preexposure to a UCS that minimizes and thereby controls the impact of the UCS.

On the other hand, Goudie et al. (Note 3) found equal attenuating effects of signaled and unsignaled preexposure to methamphetamine on the formation of a subsequent taste aversion. They suggested that since the UCS is uncontrollable in both unsignaled and signaled preexposure conditions, controllability of the UCS may be important. Subsequently these authors demonstrated that rats allowed ad libitum access to methamphetamine during the preexposure phase do not show attenuated saccharin aversions when saccharin is paired with methamphetamine injections. These data are compatible with the hypothesis that controllability of UCS onset is the important determinant of the UCS preexposure effect. A test of this hypothesis can only be accomplished by using drugs that an animal will self-administer, for example, methamphetamine. The results of such a test may be applicable only to experiments that use drugs of abuse. On the other hand, a related hypothesis that focuses on the controllability of UCS termination can be tested with a variety of aversive UCSs. In this regard, Randich (1978) found that rats permitted to terminate electric shocks during a preexposure phase showed even greater attenuation of subsequent CER conditioning than yoked controls not permitted to terminate electric shocks during the preexposure phase. Thus, giving an animal control over the termination of an aversive UCS does not eliminate the UCS preexposure phenomenon.

The UCS onset-controllability hypothesis would account for symmetrical cross-UCS effects (cf. Goudie & Thornton, 1975) if one assumed that the aversive states induced by drugs were similar in being equally uncontrollable. Of course, given this assumption, asymmetrical cross-UCS effects pose a problem, although they primarily involve the use of D-amphetamine, a drug that has both positive and negative reinforcing characteristics (Wise, Yokel, & DeWit, 1976).

Nonassociative Theories

Artificial need states. Parker et al. (1973) suggested that preexposure to addictive drugs may induce an artificial need state for these drugs. The failure to obtain a CTA would then reflect the fact that the CS predicts alleviation of withdrawal symptoms correlated with the need state. This hypothesis is of limited general applicability. In addition, LeBlanc and Cappell (1974) have shown that preexposure to amphetamine attenuates the formation of a CTA but does not induce a need state for amphetamine.

UCS novelty. Amit and Baum (1970) and Gamzu (1977; Gamzu, Note 5) suggested that the novelty of the UCS is an important determinant of associative learning. Any treatment, such as preexposure to the UCS, that reduces the novelty of the UCS

should retard the acquisition of an excitatory CR. The usefulness of this hypothesis is directly questioned by both symmetrical and asymmetrical cross-UCS effects. If one assumes that this hypothesis can be restated as "the novelty of the aversive state is important for associative learning," then it may be possible to account for symmetrical cross-UCS effects in terms of a common aversive reaction to the UCSs. However, in doing so it becomes difficult to account for asymmetrical cross-UCS effects. In this regard, Gamzu (1977) argued that asymmetrical cross-UCS effects may reflect quantitative rather than qualitative effects of the two drugs involved. For example, he argued that the dose of *dl*-fenfluramine used by Goudie and Thornton (1975) to attenuate conditioning of a taste aversion to *dl*-fenfluramine was more aversive than the dose of D-amphetamine (see also, Braveman, 1977; Cannon et al., 1977).

Although such an argument has some force, the main problem with the UCS-novelty account is that it has not been specified in enough detail to be easily tested.

Central habituation. Perhaps the most widely accepted nonassociative explanation of the UCS preexposure phenomenon is that some central habituation process occurs in response to repeated applications of the UCS during the preexposure phase and reduces the organism's responsiveness to subsequent applications of the UCS (Kamin, 1961; Mis & Moore, 1973; Taylor, 1956). This hypothesis has been stated in a variety of forms. For example, Braveman (1975) stated that an organism may habituate to the stress induced by the UCS. Similarly, it has been suggested that an organism may develop a tolerance for the UCS when drugs are used as UCSs (Cappell et al., 1975; LeBlanc & Cappell, 1974; Riley et al., 1976). Central habituation to the UCS, habituation to the stress induced by the UCS, and tolerance for the UCS are formally quite similar accounts.

It is possible that some physiological substrate, which is activated by an aversive UCS and is important for excitatory conditioning, is modified by repeated exposure to the UCS. Riley et al. (1976) suggested that this physiological substrate may involve the pituitary–adrenal axis and, in particular, the adrenocorticotrophic hormone (ACTH). For example, ACTH has been shown to be critical for normal acquisition of conditioned active and passive avoidance responses (cf. DeWied, 1964), and the release of ACTH is conditioned in CER paradigms (Bassett, Cairncross, & King, 1973; Brady, 1967) and CTA paradigms (Ader, 1977). It is also known that exposure to an unsignaled, aversive UCS often inhibits the normal release of ACTH from the adenohypophysis in response to subsequent applications of that UCS or to other aversive stimuli (Milulaj & Mitro, 1972; Munson, 1973). It is possible, therefore, that inhibition of stress-induced release of ACTH by prior exposure to unsignaled, aversive stimuli would reduce the potentiating effect that ACTH has on the acquisition and maintenance of fear-motivated behaviors. The possibility that ACTH plays a role in the preexposure phenomenon is intriguing for the following reasons. First, it would provide a common final substrate through which many aversive stimuli might act and thus a basis for the notion of central habituation. Second, some investigators (Rescorla, 1973) have obtained evidence of a preexposure effect only during extinction testing, a situation in which Weiss, McEwen, Silva, and Kalkut (1970) have shown ACTH to have maximal effects on behavior. However, the hypothesis that ACTH plays a critical role in the UCS preexposure phenomenon should be viewed with some caution, considering the lack of data.

Memorial representation. Rescorla (1974) proposed that first-order excitatory conditioning involves the construction of memories for individual events and a formation of associations (stimulus–stimulus) between such memories. Preconditioning exposure to a UCS produces a memorial representation of that UCS that may either augment or diminish the representation of the UCS used during excitatory conditioning. An unsupplemented memorial-representation model predicts no UCS preexposure effect unless UCS intensity is changed between the preexposure and conditioning phases and is thus untenable. Consequently, it seems worthwhile to

consider how central habituation and changes in memorial representation of the UCS might interact. It may be the case, for example, that animals preexposed to any intensity UCS will show an attenuation of excitatory conditioning because of central habituation but that the amount of attenuation will also be a function of changes in the memorial representation of the UCS. In general, Rescorla's view would predict that the attenuating effect of UCS preexposure should be diminished when the UCS is more intense during preexposure than during excitatory conditioning, but enhanced when the UCS is less intense during preexposure than during conditioning. In studies that used unsignaled preexposure conditions (Cannon et al., 1975; Mis & Moore, 1973) and signaled preexposure conditions (Randich, 1978), these results were not obtained. Thus, changes in the memorial representation of the UCS are unlikely to contribute to the UCS preexposure effect.

Opponent-process theory. Another nonassociative account of the decremental effect of preexposure to the UCS comes from the opponent-process theory of acquired motivation (Solomon, 1977; Solomon & Corbit, 1974)—a theory designed to explain the affective dynamics of responses to strong stimuli. The opponent-process theory holds that the relative strengths of two opposing processes, the a process and the b process, determine the affective state of an organism in response to a strong stimulus. The a process, or primary affective process, is postulated to be the emotional UCR to the UCS, for example, fear elicited by a strong electric shock. The a process is said to be stimulus locked, showing little habituation or sensitization with successive presentations of the UCS. The b process, or the opponent process, is said to be aroused by occurrence of the a process and to have an affective sign opposite to that of the a process, for example, inhibition of fear following strong shock. The b process, unlike the a process, is postulated to increase in both intensity and duration with repeated evocation, as long as the time interval between successive evocations is less than that required for the complete decay of the b process (*critical decay duration;* Starr, 1976). The algebraic summation of these two opposing affective processes results in a standard pattern of affective dynamics. When the quantity $a - b$ is positive, the animal is said to be in the A state; when the quantity $a - b$ is negative, the animal is said to be in the B state.

This model bears on the UCS preexposure phenomenon because it predicts that repeated presentations of the UCS will strengthen the b process when these presentations are separated by less than the critical decay duration. As this occurs algebraic summation of the opponent processes should result in a greatly diminished A state and in an augmented B state with a long decay time. If excitatory classical conditioning is the conditioning an A state to a nominal CS, then such conditioning will be attenuated by prior exposure to the UCS because this treatment diminishes the A state.

The opponent-process model makes a prediction that is not made by other nonassociative accounts of the UCS preexposure phenomenon. If the b process grows with repeated UCS presentations, then the conditioning of the B state should be facilitated by prior exposure to the UCS. Thus, if a nominal CS is paired with the peak of the B state in a backward conditioning procedure, conditioning of this B state should be facilitated by prior exposure to the UCS. Other nonassociative accounts of the UCS preexposure phenomenon that have been discussed predict attenuating effects of UCS preexposure on both excitatory (A state) and inhibitory (B state) conditioning. These differential predictions have not yet been tested.

Summary

The first researchers to demonstrate the decremental effect of prior exposure to the UCS on the acquisition of an excitatory CR explained this decrement in nonassociative terms (Kamin, 1961; Kimble & Dufort, 1956; Taylor, 1956). However, with the marked surge in the development of associative theories of Pavlovian conditioning in the late 1960s and early 1970s (Kamin, 1969; Rescorla & Wagner, 1972) came an attempt

to encompass a greater variety of phenomena, including the UCS preexposure effect, in associative terms.

The most viable associative explanation of the UCS preexposure phenomenon obtained in human eyelid conditioning, rabbit eyelid conditioning, CER, and CTA learning is context blocking. According to this view, prior exposure to the UCS conditions some stimulus aspect of the experimental environment, thereby blocking subsequent conditioning of a nominal CS in that same environment. A question that naturally arises is, what can be gained by the study of the UCS preexposure effect if context blocking forms the basis of this phenomenon? In other words, what implications does a context-blocking explanation have for learning theory in general?

First, a context-blocking analysis should delineate the nature of contextual stimuli that can be associated with UCSs and should determine whether responding to these stimuli can be described by the same laws that govern responding to discrete CSs. Although an influential formal model of Pavlovian conditioning (Rescorla & Wagner, 1972) has emphasized the importance of the conditioning context in an abstract sense, there have been few attempts to identify the physical aspects of the context that do become conditioned. In the absence of such attempts, potentially important differences between conditioning paradigms remain obscure. For example, interest in context blocking has called attention to the importance of handling and injection cues in the analysis of learning established in the CTA paradigm (Braveman, 1978; Rudy, Iwens, & Best, 1977; Willner, 1978). Such stimuli, for example, the handling and injection procedure that occurs between the presentation of the nominal CS and the occurrence of the UCR, have no obvious analogues in the CER or eyelid conditioning paradigms.

A context-blocking view may also provide important information concerning common elements of the UCRs elicited by different UCSs and the role of such responses in the conditioning process. Such a notion was anticipated in Konorski's (1967) discussion of the role of preparatory CRs in the conditioning process. According to Konorski, preparatory or diffuse emotional responses elicited by UCSs must first be conditioned to a nominal CS before a consummatory or specific CR can be established. Information about the similarities among preparatory responses based on different UCSs could be derived from outcomes of experiments on cross-UCS preexposure effects.

Other associative accounts of the UCS preexposure phenomenon, such as controllability of the UCS (Vogel, Note 2), remain to be more fully explored. Research based on the UCS-controllability hypothesis may establish vital links between the learned helplessness phenomenon and the UCS preexposure effect.

Nonassociative accounts of the UCS preexposure phenomenon also warrant thorough investigation because they too have important implications for learning theory. The most viable nonassociative hypothesis of the UCS preexposure effect is that some central adaptation or habituation process occurs during prior exposure to the UCS and reduces the impact of the UCS during subsequent excitatory conditioning. If central habituation proves to form the basis of the UCS preexposure effect in a given paradigm, then one should consider the possibility that a substantial amount of habituation occurs in any Pavlovian conditioning procedure that repeatedly presents the UCS. The opponent-process model (Solomon & Corbit, 1974) makes an analogous prediction, although on the basis of cancellation of a constant *a* process by a gradually increasing *b* process. In any case, the role of *b* processes in habituation of various responses is a worthwhile area for further study.

One widely studied paradigm in Pavlovian conditioning, called *blocking* (Kamin, 1969), refers to the case in which prior conditioning to one stimulus (A) markedly attenuates conditioning to an added stimulus (B) in the compound stimulus AB, as long as the UCS remains unchanged. A common assumption in all explanations of blocking (Mackintosh, 1975; Rescorla & Wagner, 1972) is that to the extent that the added stimulus, B, provides no new information about the

occurrence of the UCS (beyond that provided by Stimulus A), Stimulus B will not condition. However, if it is assumed that habituation occurs to the UCS during Stimulus-A training, then this reduced emotional responsiveness may in part be responsible for the failure to condition Stimulus B, independent of the presence of Stimulus A in either phase. This notion suggests that a group of animals receiving reinforced presentations of Stimulus C followed by reinforced presentations of the compound stimulus AB (C+/AB+) would show blocking relative to a group receiving no treatment and then AB+ training. A C+/AB+ control group is not typically incorporated in studies of the blocking phenomenon.

A habituation account of the UCS preexposure phenomenon also bears on the *unblocking* effect. It is known that unblocking, or conditioning of the added stimulus (B) in the compound AB, occurs following prior conditioning of Stimulus A when the intensity of the UCS used to reinforce the compound is increased (Kamin, 1969) relative to the intensity of the UCS used to condition Stimulus A. Similarly, Dickinson, Hall, and Mackintosh (1976) showed that unblocking occurs when Stimulus A is reinforced with two shocks and the compound stimulus AB is reinforced with only one shock; there is a relative decrease in the intensity of the UCS. The unblocking effect is typically attributed to the surprise value of the novel UCS used to condition Stimulus AB, although the mechanism of surprise remains unstated. In this regard, habituation to the UCS may provide a mechanism of surprise. If one assumes that some habituation of the UCR to the UCS occurs during conditioning of Stimulus A, the use of a novel UCS during conditioning of Stimulus AB, whether the UCS represents a relative increase or a relative decrease in intensity, may act to temporarily dishabituate the UCR to the UCS (Thompson & Spencer, 1966). This treatment would effectively act to restore the former UCR to the UCS, and depending on how much habituation has occurred and the magnitude of the dishabituation effect, would permit some conditioning of Stimulus B.

A dishabituation account of the unblocking effect also revitalizes the explanation of blocking and unblocking that can be derived from the Rescorla–Wagner (1972) model of conditioning. The occurrence of unblocking when Stimulus A is reinforced with two shocks but Stimulus AB is followed by only one shock (Dickinson et al., 1976) is problematical for this model, which assumes that only a manipulation that increases the overall level of associative strength that the UCS can support permits Stimulus B to condition. Reducing the number of shocks during AB training is not expected to produce an increase in overall level of associative strength. However, if unblocking is attributable to dishabituation, then restoration of a previously habituated UCR to the UCS should act to temporarily increase the overall level of associative strength that the UCS can support and permit Stimulus B to condition according to the general framework specified by the Rescorla–Wagner model.

The evidence presented in this review conclusively supports neither a context-blocking nor a habituation account of the UCS preexposure phenomenon; nor is it necessary to assume that a single mechanism of action is responsible for the phenomenon. Associative and nonassociative factors may both play a role in any given situation, and, indeed, the relative importance of the two may vary across conditioning paradigms. At the present time, we suffer from both a lack of understanding of basic processes and the absence of theoretical models that provide rules for combining associative and nonassociative contributions to performance established by Pavlovian conditioning procedures.

Symbolic Interactionist View of Self-Concept: Through the Looking Glass Darkly

J. Sidney Shrauger and Thomas J. Schoeneman
State University of New York at Buffalo

Research on the relationship between self-perceptions and evaluations from other people is reviewed. Studies of naturalistic interactions indicate that people's self-perceptions agree substantially with the way they perceive themselves as being viewed by others. However, there is no consistent agreement between people's self-perceptions and how they are actually viewed by others. There is no clear indication that self-evaluations are influenced by the feedback received from others in naturally occurring situations. When feedback from others is manipulated experimentally, self-perceptions are usually changed. However, methodological limitations such as the questionable external validity and strong demand characteristics of the experimental situations employed make the significance of these findings unclear. The available evidence is examined within a framework that considers the transmission, processing, and evaluation of judgments from others. Other means by which interaction may influence self-perceptions aside from direct evaluative feedback are considered.

O wad some power the giftie gie us
To see oursels as others see us!
Robert Burns, *To a Louse*

Burns's couplet expresses a concern about self-knowledge and its origins that is ancient and contemporary. Recently, a resurgence of interest in the self has flourished in many areas of psychology, especially in psychotherapeutic formulations that view cognitions about oneself as vital mediators in the maintenance and modification of behavior and in social psychological theories involving attribution, cognitive dissonance, and self-awareness. Understanding how attitudes about the self are developed and maintained has thus become increasingly important.

When people are asked how they know that they possess certain characteristics, a typical answer is that they have learned about them from other people. A more formal theoretical statement of this view has been articulated by the influential school of thought known as symbolic interactionism. This theory proffers the idea of a "looking glass self" and asserts that one's self-concept is a reflection of one's perceptions about how one appears to others. This assertion has received widespread professional acceptance and is intoned with catechistic regularity in many leading texts on social behavior (e.g., Raven & Rubin, 1976; D. J. Schneider, 1976; Secord & Backman, 1974).

Social philosophers and psychologists of the late 19th century such as Peirce (1868), James (1890), and Baldwin (1897) were precursors of symbolic interactionism in their emphasis on the self as a product and reflection of social life (Gordon & Gergen, 1968; Ziller, 1973). Cooley (1902), generally credited as the first interactionist, developed the idea of the looking glass self. He posited that the self is inseparable from social life and necessarily involves some reference to others. This process of social reference results in the looking glass self: "A self idea of this sort seems to have three principal elements: the imagination of our appearance to the other person; the imagination of his

---

judgment of that appearance, and some sort of self-feeling, such as pride or mortification" (Cooley, 1902, p. 152). According to Cooley, from early childhood our concepts of self develop from seeing how others respond to us: "In the presence of one whom we feel to be of importance, there is a tendency to enter into and adopt, by sympathy, his judgment of ourself" (p. 175). Mead (1934), the major theorist of symbolic interactionism, amplified and expanded the view of the self as a product of social interaction: "The individual experiences himself as such, not directly, but only indirectly, from the particular standpoints of other individuals of the same social group, or from the generalized standpoint of the social group as a whole to which he belongs" (p. 138). Essential to the genesis of the self is the development of the ability to take the role of the other and particularly to perceive the attitude of the other toward the perceiver. Mead's looking glass self is reflective not only of significant others, as Cooley suggested, but of a generalized other, that is, one's whole sociocultural environment. More recently, Kinch (1963) has summarized and systematized symbolic interactionist self theory by noting that it basically involves an interrelation of four components: our self-concept, our perception of others' attitudes and responses to us, the actual attitudes and responses of others to us, and our behavior.

In recent years, self theories have been proposed that do not insist on the primacy of social others as sources of information about the self. Bem (1967, 1972) has asserted that self-perception is a special case of person perception:

> Self-descriptive attitude statements can be based on the individual's observations of his own overt behavior and the external stimulus conditions under which it occurs. . . . As such, his statements are functionally similar to those that any outside observer could make about him. (1967, pp. 185–186)

Jones and Nisbett (1971) have qualified Bem's analysis somewhat by proposing that "actors tend to attribute the causes of their behavior to stimuli inherent in the situation, while observers tend to attribute behavior to stable dispositions of the actor" (p. 93). Duval and Wicklund's (1972) objective self-awareness theory also emphasizes the potential of the individual for active self-appraisal. Objective self-awareness is a state of consciousness in which attention is focused inward on the self, making the individual an object to his or her consciousness. The assumption that self-awareness is dependent on the imagination of another's views is minimized. Although these self-perception theories have stimulated considerable research, the initial justification for each view was mainly on theoretical rather than empirical grounds. Thus, some attention is given to the relevance of the data presented here to self-perception theories, although the main objective is to evaluate the evidence relevant to the looking glass self.

Information concerning the looking glass self derives from several lines of inquiry, not all of them explicitly related to this theory. Even work that has been done within the framework of symbolic interactionism suffers from a severe case of "ahistoricity," so that there is little sense of cumulative development of information. This article attempts to examine thoroughly the studies done under the auspices of symbolic interactionism. An exhaustive review of relevant studies outside of this framework cannot be claimed, however, since these come from many divergent bodies of literature.

The research presented is divided into two sections. First, studies are reported that examine feedback given in uncontrolled, naturally occurring interactions. Next, investigations of the effects of controlled feedback in structured situations are considered, with attention given to work in which feedback is purportedly based either on objective information or on more subjective judgments. Some restrictions on the types of research reviewed here should be noted. The main dependent variable examined is expressed self-perceptions. Studies exploring the impact of self-relevant feedback on other aspects of behavior are typically not covered, since it is debatable whether such changes are necessarily mediated by changes in self-perceptions. Also, although it may be argued that studies of attitude change on any topic involve some implied reappraisal of self-evalu-

Table 1
Investigations of the Relationship Between Subjects' Self-Descriptions and Subjects' Perceptions of How Others Describe Them

Study	Analysis	Subjects	Assessment dimension	Significant others	Congruence between self and perceived others' evaluation?[a]
Davidson & Lang (1960)	Correlation	203 fourth–sixth graders	Self-concept	Teacher	Yes (r = .82)
Fey (1955)	Correlation	58 3rd year medical students	Self-acceptance	Peers	Yes (r = .71)
Goodman (1973)	Correlation	185 fourth–sixth graders	Self-concept	Peers	Yes (r = .37)
Goslin (1962)	Comparison	187 seventh and eighth graders	Personality traits	Peers	Accepted subjects: yes; rejected subjects: no
Jourard & Remy (1955)	Correlation	99 undergraduates	Perception of self and body	Mothers, fathers	Yes ($.56 \leq r \leq .77$)
Kemper (1966)	Count of significant correlations	256 business men (M age = 40 years)	Self-description	Wife, boss, colleague, father	Yes (with wife > with boss > with colleague > with father: all rs $\leq .22$)
Miyamoto & Dornbusch (1956)	Count of supporting results	195 undergraduates	Personality traits	Peers, generalized other	Yes
Orpen & Bush (1974)	Correlation	14 males, 17 years old	Responsibility, sociability	Peers	Yes ($.49 \leq r \leq .80$)
Quarantelli & Cooper (1966)	Nonstatistical comparison	1,012 1st to 2nd year dental students	Self-rating on dental student – dentist continuum	Peers, instructors, wives, generalized others	Yes (high self-raters > low in mean perceived response of others)
Reeder, Donohue, & Biblarz (1960)	Nonstatistical comparison	54 enlisted military personnel	Leadership, work ability	Peers	Yes (high self-raters > medium > low in estimated group rating)
Swanson (1969)	Comparison of correlations	11 emotionally disturbed, 35 learning disabled, 35 normal children, 6–12 years old	Self-worth, self-acceptance	Parents	Emotionally disturbed: yes; learning disabled and normals: no
Teichman (1972)	Correlation	50 delinquent, 25 nondelinquent boys	Self-concept	Parents	Nondelinquents: yes ($.78 \leq r \leq .85$); delinquents: no
Walhood & Klopfer (1971)	Correlation	13 graduate students	Love, dominance	Peers	Yes ($.60 \leq r \leq .93$)

[a] For all rs, $p < .05$.

ations, the focus here is limited to changes in attitudes about the self, since there is evidence that reactions to feedback about the self differ from those about other attitudes (e.g., Eagly, 1967). A final restriction involves the area of self-presentation. Expressing one's self-perceptions in any public fashion inevitably has some potential instrumental value, and numerous investigations have focused on the functional impact of such self-statements. These studies, however, address issues that are not central to our discussion. The focus of this article is on investigations in which self-statements are perceived as fairly accurate estimates of the individual's actual attitudes and external incentives to a particular type of self-presentation are minimized.

Naturalistic Studies

Many investigations have sought support for the idea of the looking glass self in naturally occurring interactions. One group of studies has focused on the proposition that individuals' self-perceptions should be highly congruent with the way they see themselves as being perceived by others. Table 1 shows that these studies vary widely along a number of different dimensions. Most analyses were correlational, some involved statistical comparisons, and some of the earlier studies relied on nonstatistical "eyeballing" of the data (e.g., Miyamoto & Dornbusch, 1956; Quarantelli & Cooper, 1966; Reeder, Donohue, & Biblarz, 1960). Samples have been drawn from all levels of the educational system and from a variety of other populations. Evaluations by self and others have most often centered on global measures of self-concept, although some investigations have examined more specific aspects of personality and behavior. Overall, these studies show modest to strong correlations between individuals' perceptions of themselves and the way they assume others perceive them. Nonsignificant relationships have occurred in situations in which deviant groups, such as delinquents (Teichman, 1972), learning disabled students (Swanson, 1969) and sociometrically rejected students (Goslin, 1962), have been studied. The only exception to this pattern is Swanson's finding that for 11 emotionally disturbed children there was congruence between self-acceptance and perceived parental acceptance and that for 35 normal children this congruence was absent.

In addition to postulating concordance between self-evaluation and the perceived evaluations of *significant* others, Mead (1934) contended that self-concept is reflective of the perceived evaluation of a *generalized* other. Relatively few studies have examined this facet of symbolic interactionism. There is some evidence that individuals' self-perceptions are similar to their perceptions of how they are viewed by others in general (Miyamoto & Dornbusch, 1956; Quarantelli & Cooper, 1966; Reeder et al., 1960). The evidence on whether self-perceptions are more strongly related to the perceived impressions of specific others or to the perceived impressions of the generalized other, however, is contradictory (Miyamoto & Dornbusch, 1956; Quarantelli & Cooper, 1966).

The demonstration of a relationship between people's self-perceptions and how they feel others see them is not sufficient in validating the symbolic interactionist position. It is necessary, in addition, to demonstrate congruence between (a) self-perceptions and others' actual perceptions of the person and (b) perceived other-evaluations and actual other-evaluations. A large number of studies have examined the former relationship; they are summarized in Table 2. Although many of these studies are of questionable statistical and conceptual significance (Wylie, 1974), the overall pattern of the conclusions drawn by these investigations suggests much less agreement between self-judgments and actual judgments by others than between self-judgments and perceived judgments. Approximately half the studies reviewed show no significant correlations between self-perceptions and others' actual evaluations. The majority of the remaining investigations have reported either significant but low correlations or ambiguous results. There are no easily distinguishable factors that account for the presence or absence of positive associations. A wide range of subjects and evalu-

Table 2
Investigations of the Relationship Between Subjects' Self-Descriptions and Actual Descriptions of Them by Significant Others

Study	Analysis	Subjects	Assessment dimension	Significant others	Congruence between self and others' evaluations?[a]
Alberti (1971)	Correlation	656 first–third graders	Performance in role of student	Peers, teachers	With peers: no; with teachers: yes
Amatora (1956)	Correlation	400 fourth–eighth graders	22 personality traits	Peers	Yes: for boys, $.15 \leq r \leq .67$ for 19 out of 22 traits; for girls, $.15 \leq r \leq .62$ for 20 out of 22 traits
Bishop (1971)	Correlation	25 graduate students	Counseling effectiveness	Clients, supervisors	With clients: no; with supervisors: yes ($r = .41$)
Bledsoe & Wiggins (1973)	Comparison	100 ninth graders, 200 parents	Self-image	Parents	No (parents' evaluations > adolescents' self-evaluations)
Brams (1961)	Correlation	27 graduate students	Effective communication in counseling	Peers, supervisors	No
Breslin (1968)	Correlation	28 handicapped, 10–16 years old	Self-concept	Peers	No
Buckley (1970)	Comparison	22 student teachers	Self-attitude	Students	No (high self-raters equaled low in ratings by students)
Burke (1969)	% agreement	113 undergraduates	Final grade	Peers, teachers	With peers: 70%; with teachers: 60%
Carroll (1952)	Correlation	125 army enlisted men	5 personality traits	Peers	Yes ($.29 \leq r \leq .56$)
Cogan, Conklin, & Hollingworth (1915)	Average deviation of self-rankings from median ranking of subject by others	25 junior, 25 senior coeds	9 personality traits	Peers	No: mean of average deviations on 9 traits was 6.1 places
Douce (1970)	Correlation	60 female high school students	Self-esteem	Peers	No
Eisenmann & Robinson (1968)	Correlation	17 institutionalized physically disabled, 30–60 years old	Creativity	Peers	Yes ($r = .74$)
Fey (1955)	Correlation	58 3rd year medical students	Self-acceptance	Peers	No

Table 2 (*continued*)

Study	Analysis	Subjects	Assessment dimension	Significant others	Congruence between self and others' evaluations?[a]
Friedsam & Martin (1963)	Correlation, chi-square	87 medical outpatients over 50 years old	Rating of health	Physicians	Yes: corrected coefficient of contingency = .33; $\chi^2 = 5.00$, $p < .05$, for table of favorable–unfavorable self-ratings × favorable–unfavorable physician ratings of health
Goldings (1954)	Rank order correlation	20 male undergraduates	Happiness	5 "experienced judges" (experimenters who had tested subjects)	Ambiguous: for 2 judges, $r = .45$ and $.64$ ($p < .05$); for other 3 judges, p not significant (for all 5 judges, average $r = .38$)
Goodman (1973)	Correlation	185 fourth–sixth graders	Self-concept	Peers	Yes ($r = .20$)
Goslin (1962)	Comparison	187 seventh and eighth graders	Personality traits	Peers	Accepted subjects: yes; rejected subjects: no
Gray & Gaier (1974)	Correlation	7 12th-grade females, 14 best friends, 14 parents	Positive and negative traits	Peers, Parents	Yes (with parents, $r = .74$; with peers, $r = .76$)
Green (1948)	Comparison	23 Egyptian male graduate students and 23 Egyptian, British, and Greek female undergraduates	Leadership ability	Peers	No: 20 out of 23 males, 16 out of 23 females overestimated own rank as compared with group's ranking of him or her
Hamilton (1969)	Correlation	70 fraternity members	Self-esteem dominance, dogmatism	Peers	No
Hase & Goldberg (1967)	Correlation	201 1st year coed-dormitory residents	5 personality traits	Peers	Yes ($.23 \leq r \leq .56$)
Helper (1958)	Correlation	53 eighth and ninth graders	Favorableness, acceptance	Parents	With fathers: yes ($.26 \leq r \leq .44$); with mothers: no
Horowitz (1962)	Correlation	111 fourth–sixth graders	Self-concept	Peers (same sex)	Fourth-grade girls: yes ($r = .59$); all others: no

Table 2 (*continued*)

Study	Analysis	Subjects	Assessment dimension	Significant others	Congruence between self and others' evaluations?[a]
Israel (1958)	Comparison of level of self-evaluation of subjects evaluated by group as high, middle, low No. of subjects whose comparison of self versus others agreed with the others' comparisons	29 student nurses	Intelligence, leadership, orderliness, appearance	Peers	Yes: for intelligence and leadership only, subjects highly evaluated by group had higher self-evaluations No: few subjects exceeded chance accuracy in their comparisons of self versus others versus the same comparisons made by the others
Jansen, Robb, & Bonk (1973)	Factor analysis	173 graduate students	Counseling competence	Peers	No (self-ratings > peer ratings)
Jorgenson (1967)	Correlation	400 third graders	Personality traits	Peers, teachers	No
Kelman & Parloff (1957)	Rank order correlations	7 male, 8 female neurotic group-therapy patients	Behaviors in group therapy	3 observers (psychologists and social worker)	No (both before and after therapy)
Klimoski & London (1974)	Correlation, factor analysis	133 nurses	Job performance	Peers, supervisors	No
Lomont (1966)	Comparison	64 sorority, 72 fraternity members	Dominance–submission, love–hate	Peers	Yes: no significant differences between means of subjects' self-ratings and means of peer ratings
Mayo & Manning (1961)	Correlation	196 naval recruits	Effort in aviation course	Peers	Yes (r = .28)
McConnell (1959)	Comparison	137 third and fourth graders	Social acceptance	Peers	No: less than 50% females, about 33% males judged selves accurately (compared with peer ratings)
McIntyre (1952)	Comparison	224 second semester dormitory freshmen	Self-acceptance	Peers	No (high-accepted subjects equaled low in self-acceptance)

Table 2 *(continued)*

Study	Analysis	Subjects	Assessment dimension	Significant others	Congruence between self and others' evaluations?[a]
Miyamoto & Dornbusch (1956)	Count of significant results	195 undergraduates	Personality traits	Peers	Yes
Mote (1967)	Correlation	157 fifth and sixth graders, mothers	Self-concept	Mothers	Mother's satisfaction with child learning: yes; with child behavior: no
Orpen & Bush (1974)	Correlation	14 males, 17 years old	Responsibility, sociability	Peers	No
Perkins (1958)	Correlation	48 fourth–sixth graders	Self-evaluation	Teachers	Yes (r = .41)
Phillips (1963)	Correlation	96 third and 96 sixth graders	Social characteristics, school achievement inventory	Peers, teachers	Third graders: no; sixth graders: yes (with peers, r = .40; with teachers, r = .57)
Powell (1948)	Rank order correlations	140 coed-dormitory residents	Adjustment	Dorm advisors, peers	No: *Mdn ps* (from 8 dormitory corridors) $\leq$ .24
Reeder, Donohue, & Biblarz (1960)	Nonstatistical comparison	54 enlisted military personnel	Leadership, work ability	Peers	Low self-raters: yes; high and medium self-raters: no
Reese (1961)	Comparison	408 fourth, sixth, eighth graders	Self-evaluation	Peers	Curvilinear relationship: medium self-concept > high > low in amount of acceptance by others
Rokeach (1945)	No. overestimates versus underestimates (self versus average other ratings)	134 female undergraduates	Physical beauty	Peers	No: 72% of subjects overestimated own beauty
B. Schneider (1970)	Correlation, factor analysis	240 male undergraduates	Group leadership behaviors	Peers	Yes ($.25 \leq r \leq .51$); factor structure different for self-ratings and peer ratings

Table 2 (*continued*)

Study	Analysis	Subjects	Assessment dimension	Significant others	Congruence between self and others' evaluations?[a]
Scott & Johnson (1972)	Correlation	234 undergraduates	Attitudes toward 14 persons, issues, and so on	Friends	Yes ($.14 \leq r \leq .61$)
	Correlation	50 undergraduates	9 motives (needs)	Friends	Yes, for 7 of 9 motives ($.25 \leq r \leq .55$)
	Correlation	92 institutionalized youthful offenders	Attitudes toward 16 persons, issues, and so on	Work supervisors, counselors	Yes, for 8 of 16 attitudes ($.17 \leq r \leq .59$)
Todorosky (1972)	Correlation	177 sorority members	Self-acceptance	Peers	No
Tschechtelin (1945)	Comparison	1,542 fourth–eighth graders	22 personality traits	Teachers, peers	No: boys tended to underestimate self versus peers and teachers; girls tended to overestimate
Walhood & Klopfer (1971)	Correlation	13 graduate students	Love, dominance	Peers	No
Webb (1955)	Correlation	95 naval aviation cadets	Intelligence	Peers	Yes ($r = .43$)
Werdelin (1969)	Correlation, factor analysis	416 high school students	Classroom behaviors	Peers, teachers	No
Wetzel (cited in Peterson, 1965)	Correlation	72 undergraduates	Adjustment, introversion–extraversion	Peers, parents	Yes ($.24 \leq r \leq .41$)
Winthrop (1959)	Correlation	60 female undergraduates	Adjustment	Closest friend	Yes: for overall adjustment and 4 subscales, $.41 \leq r < .66$

[a] For all *r*s, $p < .05$.

(*text continued from page 552*)

ators were used, and comparisons were made on many attributes, most frequently self-esteem or task competence. Also, a number of studies have shown that perceived reactions of others are closer to self-concept than are actual reactions (Miyamoto & Dornbusch, 1956; Orpen & Bush, 1974; Quarantelli & Cooper, 1966; Sherwood, 1965; Walhood & Klopfer, 1971). The minimal associations between self-perceptions and others' actual evaluations suggest that people do not accurately perceive others' opinions of them, that these opinions minimally influence self-judgments, or, as indicated by a study by Reese (1961), that these two variables may be curvilinearly related, thus explaining why significant linear correlations do not often emerge (Hartup, 1970). Studies assessing degree of influence are infrequent and are discussed below.

The issue of accuracy in perceiving others' opinions has also been examined by the consideration of the relationship between individuals' perceptions of others' views of them and others' actual views. Of the studies assessing this relationship, some show congruence (Ausubel & Schiff, 1955; Ausubel, Schiff, & Gasser, 1952; De Jung & Gardner, 1962), some indicate partial or ambiguous relationships (Goslin, 1962; Israel, 1958; Reeder et al., 1960; Tagiuri, Blake, & Bruner, 1953; Walhood & Klopfer, 1971), and others demonstrate no association (Ausubel, 1955; Fey, 1955; Kelman & Parloff, 1957; Orpen & Bush, 1974). Most of the studies showing congruence have involved judgments of highly evaluative characteristics such as liking by the other person, whereas those showing minimal associations have typically involved more content-specific judgments. Ability to predict peers' liking increases with age, at least from the lower grades through high school (Ausubel & Schiff, 1955; Ausubel et al., 1952; De Jung & Gardner, 1962), reflecting perhaps a more extentive interaction with those judged, more frequent expression of interpersonal preferences, or greater sensitivity to interpersonal cues. Also, whether one is predicting positive or negative feelings may be important; people seem to be better able to predict who likes them best as opposed to who likes them least (Tagiuri et al., 1953). That self-perceptions are consistently more strongly correlated with people's perceptions of how they think others view them than with how others actually view them suggests that the tendency to assume greater similarity between one's own and others' attitudes than actually exists (e.g., Newcomb, 1961) extends into the area of attitudes toward oneself. Thus, subjects' self-evaluations may be weakly related to others' opinions of them because they frequently do not know what others' opinions are.

Since the studies reported thus far show no direction of causality or change over time, it is impossible to decide whether the actual or perceived evaluations of people by others are a cause or effect of how they perceive themselves. If one is to infer that others' judgments influence self-perception, assessments must be made at different times to see if self-perceptions change in the direction of others' earlier evaluations. Almost all of the relevant investigations have examined short-term changes in self-evaluation in relation to actual or perceived evaluations by others. Sherwood (1965) had sensitivity training participants rate themselves on a set of bipolar trait scales during the second day of a 2-week program. At the end of the program they rated themselves again, rated how they felt other group members would rate them, and rated other group members on the same set of dimensions. The ratings of a person by others were more similar to his or her self-ratings at the end of the program than to initial self-ratings. Since others' ratings were not obtained at the outset, one cannot infer that they actually influenced self-ratings. Instead, both the subject and other group members may have observed and responded to changes in subjects' presentation of themselves as the sessions continued.

Rosengren (1961), in a study of 10 institutionalized preadolescent boys with emotional disturbances, obtained self-ratings and ratings by peers over a 1-year interval. He found that for the post- as compared with the preratings, self-ratings were more similar

to both subjects' perceptions of others' ratings of them and others' actual ratings of them. Although these subjects did see themselves more similarly to the way they were seen by others, the critical comparison showing that self-ratings in the second evaluation became more similar to others' initial evaluations of them was not made.

The most sophisticated naturalistic investigation to date remains an early study by Manis (1955). Male undergraduates assigned as dormitory roommates rated themselves, their ideal selves, and their roommates at the beginning of a semester and after 6 weeks. Based on sociometric choices at the beginning of the first sessions, a friend and a nonfriend were designated for each subject. Subjects' self-perceptions and their friends' perceptions of them were more similar after their final rating than after their first. The most important finding was that subjects' final self-ratings were more similar to others' initial judgments of them than were their initial self-ratings. Furthermore, others' second ratings of a subject were no more similar to the subject's initial self-perceptions than were their first ratings, suggesting that others' impressions were not substantially influenced by the subject's initial self-evaluation.

Although these data suggest that individuals do change their self-perceptions in the direction of others' opinions about them, methodological limitations make this conclusion equivocal. Most significantly, subjects' self-perceptions changed in the direction of friends' initial judgments of them only when the designated friend had initially described them more favorably than subjects had described themselves. When their designated friend described them less positively than their own self-perceptions, there were no increases in the similarity of their self-descriptions. A friend who views subjects more positively than the subjects view themselves would be likely to reciprocate the subjects' friendship more than someone who views them less favorably than they view themselves. Learning that they have chosen as a friend someone who also likes them may enhance people's feelings of interpersonal perceptiveness and social competence and cause them to raise their self-evaluation.

Even if Manis's results indicate that a friend who describes a peer positively influences the peer's self-perceptions, the nature of the changes generated remains unclear. Subjects may either change the overall favorableness of their self-ratings to more closely match that of their evaluators, or they may change their assessments on specific dimensions so that the pattern of their self-descriptions across dimensions becomes more similar to that of their evaluators. This distinction raises the issue of whether the influence of others' assessments extends beyond the general evaluative level to more specific elements of the dimension being assessed. Perhaps when people are reacting to others' evaluations of them, the principal or even exclusive information that they process is whether they are being perceived in some globally positive, negative, or neutral way.

The only long-term longitudinal study that has been reported involved self-ratings and ratings by peers and teachers of children in the first and second grades who were later reassessed in the fifth and sixth grades (Trickett, 1969). Neither peer nor teacher ratings from the initial assessment were significantly correlated with self-ratings in the second assessment. Children's perceptions of how peers saw them in the initial assessment were uncorrelated with their self-perceptions in the second measurement. Although the author implied some causal influence of others' ratings (particularly those of teachers) on later self-perception, this is difficult to detect in the data. The absence of such an effect is not surprising in light of the fact that by the time subjects were in the later grades they had been exposed to a number of different peers and teachers, whose influence was impossible to gauge.

The numerous naturalistic studies that have been undertaken have not, by and large, contributed substantially to an understanding of the extent to which others' perceptions influence self-judgments. Currently, there is little evidence that in their ongoing social interactions people's views of themselves are shaped by the opinions of others. This is due

primarily to the lack of repeated assessments of self-perceptions and others' perceptions whereby movements of one toward the position of the other could be determined.

Other issues are also important in evaluating the naturalistic data. Many investigations may not have examined situations in which the input of other people was maximal. For instance, most studies have used late adolescents and adults as subjects. If these individuals are in stable life situations, they may be more likely to maintain relatively solidified self-images. The impact of others' opinions could possibly be enhanced and more pronounced if adults were studied in unfamiliar situations in which their norms for self-evaluation and the behavior patterns that they displayed were in a state of flux, as in Manis's (1955) study of incoming college freshmen in dormitories. It also seems likely that younger people are more susceptible to external influence in developing their self-concept than are older individuals.

A final consideration in assessing the work reviewed above concerns the individuals who are sources of feedback and their relationship to the subjects studied. Although peers are the most commonly used and are, in many cases, perhaps the most appropriate sources of evaluations, more attention should be given to the actual degree of interaction between them and the people whose self-perceptions are being assessed. Membership as a peer in a group of students or workers does not necessarily demand that colleagues offer appraisals to one another. For both children and adults, a relatively small number of people may serve as significant sources of evaluative feedback. In most studies it is the researcher who decides who the subjects' significant others are, and in many cases this designation may be off the mark. Investigations that attempt to identify the significant others of a given population (e.g., Denzin, 1966) would be useful preliminary steps in future naturalistic investigations.

Studies of Controlled Feedback From Others

Although researchers have employed a wide range of specific procedures for assessing the role of controlled feedback on judgments of others, most studies have followed one of two paradigms, which differ mainly in the extent to which the evaluator's judgments are based on objective data. In the first type of study the feedback received is purportedly based on tests of personality or competence. Typically, subjects describe themselves on the attributes assessed by the tests, then take the tests, receive feedback about their performance either immediately or within a week or two, and finally reappraise themselves. This procedure has been employed not only in specific efforts to assess the symbolic interactionist position but also in studies examining the effects of change in self-evaluation on other aspects of behavior, with change in self-evaluation often examined principally as a manipulation check. In the second type of study, feedback is based on the subjective impressions of other individuals who have no specific knowledge of objective assessment results. These studies have varied in the extent to which the other person is presented as having expertise in the topics considered.

The most elementary question typically asked in this research is, Will individuals modify their self-descriptions in the direction of the feedback they receive? The most elementary answer is *usually*. Such changes have been shown for numerous populations and for many different attributes, from competence in public speaking (Videbeck, 1960) and physical skills (Haas & Maehr, 1965) to a variety of personality traits (e.g., Backman, Secord, & Pierce, 1963; Binderman, Fretz, Scott, & Abrams, 1972; Cooper & Duncan, 1971; Eagly, 1967; Evans, 1962; Harvey & Clapp, 1965; Harvey, Kelley, & Shapiro, 1957; Regan, Gosselink, Hubsch, & Ulsh, 1975; Shrauger & Lund, 1975; Snyder & Shenkel, 1976; Steiner, 1968). In almost all cases changes in self-perception have been judged by modifications in verbal self-descriptions made immediately following others' evaluations and in the presence of the evaluator.

Although controlled feedback from others typically produces some changes in people's self-descriptions, several factors influence the extent of such changes. These include the

discrepancy of feedback from subjects' self-perceptions, favorableness of feedback, characteristics of the evaluator, consensual validation of the judgments given, and attributes of those evaluated. After these factors have been examined, some general observations on the significance and limitations of studies employing manipulated feedback are considered.

Discrepancy of Feedback From Self-Perceptions

The amount of discrepancy between others' evaluations and one's own self-perceptions has been examined in several studies. Bergin (1962) found that the credibility of feedback influenced the relationship between discrepancy and self-perception changes. With a high-credibility source, increases in discrepancy resulted in greater changes in self-relevant attitudes, whereas for a low-credibility source the tendency was for greater credibility to produce less change. Although not wholly consistent, other results have suggested that when others' evaluations are purportedly based on objective test data, self-perceptions change more as the discrepancy from initial perceptions increases (Binderman et al., 1972; Eagly, 1967; Gerard, 1961; Johnson, 1966). However, Gerard found that this occurred only when subjects felt that the feedback they had received would be made public, and Eagly found that changes increased from low to moderate but not from moderate to high levels of discrepancy. Johnson found a curvilinear trend, with attitude change first increasing with increased discrepancy and then decreasing. In contrast with the findings based on objective test data, when feedback was based on subjective ratings of a personality dimension made by subjects' classmates, changes in self-evaluations were not enhanced by increased discrepancy between their judgments and subjects' initial self-perceptions (Harvey & Clapp, 1965; Harvey et al., 1957). Although many factors may differentiate these studies from one another, they are generally consistent with Bergin's argument about the role of credibility and suggest that for feedback that diverges substantially from one's views to have a strong effect on self-evaluations, it must be perceived as being based on clear objective information.

Favorableness

Several studies have examined amount of change in self-perceptions as a function of feedback favorableness. Some of these studies involved the "Barnum effect," that is, the acceptance of bogus personality feedback (Meehl, 1956). Most such investigations indicate that favorable information is more readily accepted than unfavorable information (Sundberg, 1955; Halperin, Snyder, Shenkel, & Houston, in press; Mosher, 1965; Weisberg, 1970), with a few showing no differential acceptance (Dmitruk, Collins, & Clinger, 1973; Evans, 1962). These studies' significance is questionable, however, since they involved no preassessments of subjects' self-evaluations and may have reflected the greater comparability between positive information and initial self-perception than between negative information and initial self-perceptions.

A few studies have attempted to control for the discrepancy between feedback and initial impressions. Steiner (1968) examined changes in self-ratings on bipolar traits and found that positive feedback produced greater changes than negative feedback, when feedback was based on upper level undergraduates' interpretations of self-report tests. Another study (Snyder & Shenkel, 1976) attempted to control for the "initial truthfulness" of the information evaluated and found no differences in the acceptance of positive or negative feedback given by the graduate student and based on projective tests.

Turning to studies in which feedback was not based on personality test results, we find that most were not designed to assess differences in reactions to equally discrepant positive and negative evaluations (Haas & Maehr, 1965; Jones, Gergen, & Davis, 1962; Maehr, Mensing, & Nafzger, 1962; Papageorgis & McCann, 1965; Videbeck, 1960). Two careful investigations that did examine initial self-perceptions produced inconsistent findings similar to those of Steiner and Sny-

der and Shenkel just discussed. Eagly (1967) found no differential acceptance of feedback from a trained rater with regard to subjects' assertiveness or submissiveness. Harvey and Clapp (1965), however, found that students changed their self-ratings on a set of bipolar adjectives more when they had received positive feedback than when they had received negative feedback from classmates. The evaluators in Eagly's study may have had more legitimized expertise than those in Harvey and Clapp's study, and the same may have been true in the Barnum effect study of Snyder and Shenkel (1976) versus that of Steiner (1968). These results may suggest that subjects are reluctant to accept unflattering information about themselves unless they feel that the source of that information has a particularly strong basis for judgment. The inconsistency of these findings, however, suggests that the differential acceptance of positive versus negative information may depend on a variety of parameters. Eagly and her colleagues have shown, for example, that positive information is readily accepted if the recipients of the information do not expect to be evaluated again (Eagly & Acksen, 1971) and if they have no choice over the information they have received (Eagly & Whitehead, 1972). Other factors such as the strength of the subject's initial self-perceptions and the attributes on which feedback was given may also be relevant here.

Evaluator Characteristics

The most systematic investigation of factors affecting the influence of an information source involved several studies by Webster and Sobieszek (1974), who examined subjects' responses to evaluations of their ability on a perceptual task. Each subject worked with a partner, and both subjects' initial performance was judged by an evaluator whose apparent competence on the task was varied. The impact of the evaluator's assessment on subjects' self-perceptions was not measured directly, but was inferred from the extent to which subjects acquiesced to their partners' judgments on a subsequent set of items. The evaluator's judgments had more effect on rate of acquiescence when the evaluator was presented as very competent as opposed to moderately competent and had no effect when he was presented as incompetent. Manipulation of more general aspects of the evaluator's competence by presenting him to high school subjects as either a college junior or an eighth grader produced no differential changes in acquiescence level.

Other investigators have also examined the effects of manipulating general competence. Whether a test evaluator was a PhD or a counseling practicum student influenced the degree of acceptance of bogus personality feedback if that information was highly discrepant from the subject's initial self-perception but not if it was less discrepant (Binderman et al., 1972). Whether a person received ratings on adjective dimensions from an acquaintance or from a stranger in his or her class had no effect on the degree of change in subsequent self-ratings (Harvey et al., 1957). Although it is difficult to develop generalizations from such scattered findings, these data suggest that others' expertise or competence has an impact on the acceptance of their evaluations only when that competence is specifically relevant to the judgment being made.

Consensual Validation

Another aspect of the credibility of information received involves the extent to which it is validated by others. Presumably, as a larger number of individuals reflect a particular perception to the subject, the likelihood that the subject will incorporate that perception is increased. Following this assumption, Backman et al. (1963) found that bogus personality feedback had less effect on college students' self-ratings as a greater number of significant others were viewed as agreeing with the subject's initial self-perception. The specific relevance of the number of others who hold an opinion is unclear, however, since neither the salience of the dimensions to the subjects themselves nor the strength of their own self-perceptions was assessed. In another study, junior high school boys were given feedback about their physical skills by either one or two experts (Haas &

Maehr, 1965). Initial postfeedback ratings did not differ as a function of the number of raters, but self-ratings made 6 weeks after the experts' judgments showed greater changes on the attributes evaluated for the group judged by two experts. Since there was no condition in which consistent feedback was repeated by a single judge, it is not certain that it was a second person as opposed to a repetition of the communication that was the critical factor in enhancing feedback. This is an important issue, since there is some evidence that the repetition of an evaluation by the same evaluators enhances changes in self-evaluations (Kinch, 1968). Thus, there is no clear evidence that increasing the number of people who make an evaluation enhances the likelihood that it will be accepted.

The consistency of feedback across different evaluators has also been examined. Although there has been some suggestion that people respond more strongly to feedback that is consistent than to feedback that varies from evaluator to evaluator (Sherwood, 1967), other findings offer little support for this view (Kinch, 1968; Sobieszek & Webster, 1973). Because of the wide variation in the methodology of these studies, it is impossible to determine which differences among them account for the inconsistency in findings. However, given the ambiguous nature of these results, plus the fact that multiple and inconsistent evaluations may be frequent in real-life interactions, more careful examination of how evaluative information is combined and integrated seems warranted.

Self-Evaluator Characteristics

There is some evidence that individuals differ in their receptivity to information about themselves. The main characteristic that has been examined in this regard is level of self-esteem, perhaps because most of the work on response to others' feedback has focused on highly evaluative information. There is some consistency in the finding that individuals who have generally low self-esteem are more influenced by negative feedback from others and less by positive feedback than are individuals with high self-esteem. This has been shown even when subjects' initial self-perceptions about the specific attributes evaluated were comparable, and it has been demonstrated for judgments of assertiveness–submissiveness (Eagly, 1967), social sensitivity (Shrauger & Rosenberg, 1970), and several other personality traits (Harvey & Clapp, 1965). The only instance in which such a differential acceptance was not demonstrated was for self-awareness (Shrauger & Lund, 1975).

Studies of other individual differences in recipients have been more episodic. Gerard (1961) found that a self-report measure of susceptibility to social influence predicted degree of change in self-perception, but only when the evaluation from others was supposed to be made public. People who had a less well-developed sense of self or a lower level of ego identity (Erikson, 1956) changed their self-evaluations more following success or failure feedback on an intellectual task than did those at higher levels of ego identity (Marcia, 1967). Harvey, Hunt, and Schroder (1961) reported that levels of concreteness–abstractness in cognitive processes predicted the extent of changes in self-descriptions following personality test feedback. These data indicate that in the future, precise appraisals of the impact of others' judgments on self-perceptions will require acknowledging the association between subject characteristics and the nature of the judgments given.

Significance of Manipulated Feedback

Having considered some factors that can affect the impact of others' ratings, we turn to an examination of the broader significance of feedback manipulation studies, particularly the degree of influence that feedback in such studies has been shown to have. Issues to be considered here are how long feedback effects last, their situational specificity, and the influence of feedback about a specific attribute for self-appraisal on other attributes.

One important but relatively neglected issue is the longevity of the impact of others' evaluations. Only two studies have examined

the effect of others' appraisals over time. In one investigation, subjects were given positive or negative feedback about physical skills by an expert, and their self-perceptions were reassessed immediately and after 1 day, 6 days, and 6 weeks (Haas & Maehr, 1965). Both positive and negative evaluations affected self-perceptions, and these effects were maintained over the 6-week period, although they appeared to diminish over time. Changes in dimensions not specifically evaluated were evident immediately after the evaluation, but were insignificant thereafter. Hicks (1962) gave subjects feedback that classmates judged them more favorably than their own self-perceptions on a group of personality traits. Two days after the initial evaluation, subjects were more likely to have raised their self-judgments on the elevated traits than on the control traits, although this difference did not hold after a week. Thus, the minimal evidence available on this issue suggests that the impact of others' judgments on self-perceptions holds over short periods of time but tends to diminish as time passes.

Also relevant in assessing the importance of feedback from others is the extent to which the effect of feedback generalizes from focal attributes to other characteristics. The three studies that have examined this effect used expert sources and systematically varied the relatedness of secondary attributes to the focal dimension (Haas & Maehr, 1965; Maehr et al., 1962; Videbeck, 1960). They found, not surprisingly, that judgments changed more on the dimension that was evaluated than on the one that was not (Maehr et al., 1962) and that those changes that did occur in other dimensions dissipated over time (Haas & Maehr, 1965). Therefore, relatively little information exists regarding the manner and extent to which content-focused evaluations are generalized to other characteristics of oneself.

Situational factors may also influence the degree of acceptance of others' self-evaluations, since the functional utility of accepting or rejecting others' impressions may vary from situation to situation. When college students feel that evaluations of their performance on a test are going to be made public, for example, they change their self-perceptions regarding that attitude more than do subjects who feel their responses will be known only to themselves (Gerard, 1961). Eagly and Acksen (1971) found that individuals changed their self-perceptions more in the direction of negative information and less in the direction of positive information when they felt that they would be retested on the attribute on which their performance was assessed, as compared with when they felt no retesting would occur. Positive attributes may be accepted and negative attributes may be fended off if there is no immediate prospect that the accuracy of these self-enhancing beliefs will be challenged. Other potential costs and gains of accepting or rejecting others' evaluations might also be envisioned. For instance, acknowledgment of certain positive attributes might be accompanied by the anticipation of favorable future outcomes or of increased demands from others. Similarly, the endorsement of negative attributes might lead to the anticipation of social rejection or loss of other favorable outcomes. In examining such problems it is important to distinguish between self-presentation and self-perception, since certain external factors might influence the manner in which people present themselves without affecting their actual self-perceptions.

The factors that most limit the interpretation of these manipulated feedback studies are the demand characteristics of the situation in which changes in self-perception are assessed. Invariably the appraisal of changes in self-evaluation was made in the presence of the evaluator or experimenter. When the evaluator is present, subjects who do not change their self-perceptions directly discredit the evaluator's appraisal, which may be difficult, particularly if the evaluator is presented as an expert. Even when evaluators are absent, experimenters may be perceived as being likely to communicate with them. Very rarely are there clearly reported efforts to disguise the postmanipulation self-appraisal process (Shrauger & Rosenberg, 1970).

One major way that the significance of manipulated feedback studies might be en-

hanced would involve making the assessment of change less reactive and more subtle. For example, the appraisal might be woven into some other aspect of the experiment supposedly unrelated to the portion in which feedback was given, as has been done in counterattitudinal advocacy studies (e.g., Rosenberg, 1965; Hendrick & Seyfried, 1974). Another possibility is to have the final self-evaluation made after an initial "debriefing," with the evaluation presented in the context of an appraisal of the effects of psychological experiments on individuals' attitudes and feelings.

A final issue in manipulated feedback studies is whether changes in self-evaluation are specific only to the self or can reflect modifications in judgments of others as well. There is evidence (Bramel, 1962; Edlow & Kiesler, 1966; Steiner, 1968) that when people are confronted with information discrepant from their self-evaluations, they not only change their self-evaluations but also modify their evaluations of others on the attribute judged. This may reflect a process of defensive projection or simply a change in the criteria they use for evaluating the attribute in question. Unfortunately most studies have looked only at shifts in the absolute level of self-judgments and not at changes in judgments of self relative to others. Such relative appraisals may be at least as significant as absolute judgments. Therefore, the effect of feedback on judgments of others as well as of oneself should be evaluated.

Discussion and Conclusions

The numerous studies of naturalistic and manipulated feedback that we have reviewed have had much to say about the relationship between others' judgments and self-appraisals; it is unfortunate that the flaws and limitations of these investigations have rendered the significance and validity of their findings questionable. Although there is evidence that individuals' self-perceptions and their views of others' perceptions of them are quite congruent, there is less evidence that self-perceptions are related to or influenced by others' actual perceptions. None of the studies of naturally occurring interactions were designed so that they would demonstrate unequivocally that receiving content-focused feedback from others leads to corresponding changes in one's own self-perceptions. In contrast, there is ample evidence of changes in self-perceptions following controlled feedback in laboratory settings. However, the importance of these findings is unclear because of the short-term nature of most assessments and the potential effects of demand characteristics. In evaluating the contributions and limitations of the available research, we give some attention to how information from others about the self is transmitted, received, interpreted, and acted upon. These are aspects of social self-perception that have for the most part been neglected by researchers in this area.

Availability of Evaluative Information

That there is minimal agreement between individuals' judgments of others' perceptions of them and their actual perceptions suggests that the communication of feedback to others may often be infrequent or ambiguous. Although norms regarding the evaluation of other people's behavior probably vary widely across different subcultures and situations, strong sanctions are often maintained against making direct appraisals, particularly when they are negative. In some of the only research on the communication of evaluations, Blumberg (1972) found that people report inhibiting the direct communication of all types of evaluations to others, particularly if it is negative or if the recipient is not known well. Barriers to direct expression can be found in intimate relationships as well as in more impersonal social interactions. This "not-even-your-best-friend-will-tell-you" phenomenon has been noted by Goffman (1955), who pointed out that unfavorable evaluations of close associates are typically given only when directly solicited and that in such a situation, chances are that the asker has already made some negative self-appraisal. Perhaps this accounts in part for the popularity of sensitivity training, in which people have the privilege of finding out what others

really think of them, and of assertiveness training, in which they can learn to communicate their true feelings about others.

To understand the real impact of others' opinions, one must determine how frequently such opinions are communicated directly in people's everyday social interactions. Who gives evaluations? On what dimensions? Under what circumstances? How often and how explicitly? The answers to such questions would facilitate an assessment of the relative influence of others' judgments on self-perceptions, as opposed to the opposite influence of self-perceptions on the perception of others' judgments. When information from others is not explicit, its interpretation may depend substantially on one's own self-perception on the attribute being assessed. In clinical contexts, for example, if people have concerns about what others think of them, it is frequently assumed that their inferences about others' feelings reflect a projection of their own self-evaluations.

It is quite likely that direct feedback occurs extensively in the socialization of young children by parents and other adults. During the process of language development, for instance, it seems certain that children come to model the construct system of those around them and to apply these constructs to themselves. Symbolic interactionists (Cooley, 1902; Mead, 1934) and self-perception theorists (Bem, 1967, 1972; Duval & Wicklund, 1972) alike have discussed the importance of preschool interactions in the development of a concept of self. It is surprising, however, that an empirical literature substantiating these arguments is nonexistent. Naturalistic studies of self-concept and perceived or actual assessments by others pick up developing selves as they enter the captive environment of elementary school. The subjects in these studies are typically in at least third or fourth grade (see Tables 1 and 2); only two studies have used first graders (Alberti, 1971; Trickett, 1969). Studies of controlled feedback almost exclusively use undergraduates. Since the preschool years are so vital to theories of the development of self-concept, it seems imperative that this period be attended to empirically. However, this may be easier to recommend than to implement. Trickett, for example, has noted the difficulties encountered in assessing the self-concept of first graders, which means that new and imaginative methods are necessary in this regard. Furthermore, recent work raises questions about whether young children possess the abstract concepts necessary to process information from others and use it in forming perceptions of themselves (Herzberger, Note 1). A naturalistic study of parent–child evaluative interactions might be a desirable first step in determining just what kind of feedback is given in the earliest stages of life.

Finally, in considering the availability of information from others it is important to recognize that people who are evaluated may help to determine how much evaluative information they receive. People's frequency of social interaction, how directly they ask for information, and how much they behave in ways that might elicit others' comments may all affect the amount of evaluative feedback received.

Interpretation of Information From Others

Although it is likely that people differ in their interpretations of others' feedback, particularly if that feedback is not explicit, these differences have not been explored extensively. People may disagree about what cues from others constitute an evaluation. And even when cues have been identified, people may differ in the inferences or conclusions they draw from these cues about others' judgments of them. For instance, it might be important to examine the extent to which information is considered principally for its specific content or for its evaluative meaning. To date the evidence suggests that content-specific feedback changes self-descriptions principally for those attributes on which feedback is given and only minimally on other attributes (Haas & Maehr, 1965; Videbeck, 1960). However, the nature of the situation in which these data were obtained may have maximized the impersonal, objective quality of evaluations and minimized the generalization that can occur in other contexts.

Characteristics of the evaluator may also be significant in determining the extent to which information is accepted. To date examinations of evaluator competence (Webster & Sobieszek, 1974) imply that only competence relevant to the attribute being judged has real impact on the acceptance of information. Expertise of the evaluator may be more complex, however, when the attributes judged do not involve specific, clearly defined skills. In these more subjective judgments, evaluators' competence may be judged more on global indices of status or on the extent to which they are perceived to hold norms similar to one's own on the dimensions in question.

A more situational aspect of the evaluator's competence involves whether or not the evaluator has a sufficient sample of one's behavior to make an adequate appraisal. Even if an appraiser is viewed as a good judge, his or her evaluation may be discounted if it is based on a limited or unrepresentative sample of behavior. Wyer, Henninger, and Wolfson (1975) showed, for example, that observers were much more likely to base their judgments on the limited behavior sample that they observed than were actors, whose self-appraisals were based less on that specific behavior sample and more on previous experiences.

Finally, the interpretation of the evaluation may depend on a perception of how candid other people are being. If one believes that there is some ulterior motive in making the evaluation (e.g., ingratiation or one-upmanship), it may not have as much effect on one's self-perception as a communication interpreted as more genuine.

Comparison With Self-Evaluations

An important aspect of others' judgments is how closely they agree with one's initial self-appraisal. Although judgments that match an initial self-perception may do little more than fortify this perception, judgments that are at variance frequently set up some dissonance or tension that requires cognitive reappraisal. There is an implicit disagreement between symbolic interactionist and self-attribution theories as to how such discrepancies are resolved. The symbolic interactionist view implies that such discrepancies are typically dealt with by changing one's self-perceptions, whereas self-attribution theories suggest that people have a reasonably clear and stable picture of themselves and may not readily conform to the discrepant appraisal of another individual.

The extent to which self-perception is maintained in the face of contradicting information from others presumably depends on the certainty of an individual's initial self-perceptions. Several factors may influence people's assuredness about their self-perceptions, all of which are related to opportunities for examining their own behavior. One factor is the salience of the dimension on which a judgment is made. Individuals are expected to have more clearly developed opinions about themselves on dimensions that are more important to them. A second aspect regarding the opportunity for observation may be the degree to which the person can compare his or her behavior with that of other people (cf. Festinger, 1954). Impressions may be more firmly established if people have the chance to compare themselves with other individuals. However, the opportunity for such comparisons may vary depending on the dimension being judged. A final determinant of assuredness may be the clarity of the criteria against which attributes are judged. A person is more likely to have a firmly established self-appraisal on an attribute that has a very clear public definition. One reason for children's potential susceptibility to self-concept molding may be their lack of clear criteria for defining particular characteristics. This may also account for the clinical observation that negative global self-perceptions (e.g., "I am rotten" or "I am a total failure") are resistant to change without exploration of what those attributes actually entail.

One complication in assessing the impact of others' feedback is that some changes in self-perception might be attributed to input from others when in fact they really reflect changes in individuals' independent appraisals of themselves. In the naturalistic studies

cited previously, changes toward others' perceptions could be accounted for by the individuals having changed or reappraised their own behavior. Certainly there is little in this literature that would negate the potential significance of the claim of self-perception theories that most self-knowledge comes from direct observation of one's own actions.

Maintenance of Changes

As previously mentioned, there is little evidence of the long-term effects of others' judgments on self-appraisals, and more adequate investigations of these effects are clearly required. Although these investigations would ideally involve naturally occurring interactions, manipulated feedback designs could also be employed. The use of negative feedback in such studies would, of course, be unacceptable ethically, but the effects of positive feedback could feasibly be investigated.

Long-term investigations are particularly important, since at least three processes may mitigate the impact of others' evaluations over time. First, discrepant feedback tends to be distorted so that it becomes more congruent with one's own initial self-perceptions (Harvey et al., 1957; Steiner, 1968; Suinn, Osborne, & Page, 1962). This tendency toward distortion has been demonstrated in experimental situations, although it is unclear how extensively such distortions occur in real-life settings.

A second mitigating factor may be that evaluations from another person may sometimes induce people to change their behavior in an opposite direction. If, for instance, an individual were evaluated as being self-centered but did not like that attribute, he or she might expend a special effort to be more altruistic and accordingly strengthen this perception of altruism. It has been shown that when subjects are told that they are making shorter or slower responses than those of other individuals, they lengthen and speed up their subsequent responses (Burnstein & Zajonc, 1965; Kleinke, 1975). Thus, the long-range impact of others' judgments may sometimes be to produce either no change in self-ratings or even changes in the opposite direction.

A third long-term effect of others' feedback may be that people change their social interactions so that they minimize their exposure to evaluators or to situations in which such feedback is likely to occur. Conceivably these mitigating long-term effects could be offset by an opposing tendency for people to change their behavior and also their self-perceptions to conform to others' role expectations. Unfortunately there are yet no investigations that have sorted out these potential outcomes.

Some Neglected Aspects of Others' Influence

It should be noted that empirical investigations of Mead and Cooley's looking-glass-self hypothesis have explored almost exclusively the impact of direct feedback from others. There may, however, be several less direct but equally important effects of others' judgments on self-perception. Simply being in the presence of others may influence the manner in which people behave (Goffman, 1959) and presumably come to evaluate their own behavior. At a conscious level one might deliberately enhance socially desirable and minimize socially undesirable behaviors when in the presence of others, and such changes could influence how one saw oneself. Less deliberately controlled aspects of behavior may also be affected by others' presence, as suggested in studies of audience effects on performance (e.g., Zajonc, 1965) and on self-evaluations of competence (Shrauger, 1972). Also, as Mead's (1934) notion of the generalized other implies, the physical presence of others is not imperative, so long as the perceiver can manage a mental impression of them.

Other individuals may also influence one's self-judgments by the manner in which they interact with people. Whether or not one receives help from a co-worker, for example, has been shown to affect one's subsequent self-esteen (Fisher & Nadler, 1974, 1976). In certain role relationships, such as that between a boss and subordinate, many interpersonal behaviors become quite clearly pre-

scribed. The nature of these interactions may convey to the individuals involved a certain degree of competence, or self-worth, without any explicit communication of these qualities over occurring. Although such processes have been described often in role theory (Goffman, 1955, 1959; Scheff, 1966), they have much less frequently been explored empirically, particularly with reference to their effects on people's self-perceptions.

A third indirect way that social interaction may influence self-perceptions is by affording the opportunity for people to compare their behavior with that of other people. Social comparison obviously requires the presence of other people at some point. It does not, however, prevent people from being active, reflective observers of their own behavior. The observance of others' behavior provides relative standards against which one's own actions and attributes may be judged. Although the significance of such comparison processes has long been recognized, few studies have explored how attributes of those against whom one compares oneself influence self-evaluation (Fontaine, 1974; Morse & Gergen, 1970; Strong & Gray, 1972). Morse and Gergen's investigation found that job applicants' judgments of themselves were substantially influenced by the apparent competence and appearance of other potential applicants. Perhaps even in situations that do not pull so explicitly for social comparisons, the observation of others' actions affects one's self-perceptions.

Finally, other people may indirectly affect one's self-perceptions when they are observed making evaluations of other individuals. Even if people do not receive feedback directly, observing someone make a judgment of another individual may provide indirect information about how they are viewed by the evaluator. How much this actually occurs depends of course on how explicit the criteria for evaluating the other person's behavior are and on the degree to which one sees similarity or dissimilarity between one's own behavior and that of the person being evaluated.

In sum, it may be that the aspect of the looking-glass-self hypothesis that has been most frequently examined, the effect of direct feedback from other people, reflects only one of the ways that interaction with others has an impact on self-judgments. Furthermore, this means of influence may well be of no greater importance than the others. The relative ease with which direct evaluation can be explored ought not to preclude the examination of other viable aspects of social interaction that may also lead to the modification of self-evaluations.

Sex Differences in Childhood Psychopathology: A Review

Robert F. Eme
North Central College

Sex differences in the major categories of childhood behavior disorders most relevant to the issue of continuity between child and adult disorders are reviewed. Explanations for these differences are explored with attention given to both the different experiences and the different endowments of the sexes. These differences are then compared and contrasted with sex differences in adult psychopathology.

Although the sex differences in disturbed adults, both treated and untreated, have been extensively examined (Chesler, 1972; Dohrenwend & Dohrenwend, 1969; Garai, 1970; Gove & Tudor, 1973), sex differences in children appear to have been accorded only one such examination (Gove & Herb, 1974). Furthermore, this review is beset by the same limitation as part of a similar review of the adult literature by Gove and Tudor (1973), namely, as Dohrenwend and Dohrenwend (1975) suggested, the authors relied almost entirely on role theory to explain the sex differences, arguing that at some time or place one or the other sex is under greater stress and hence more prone to psychiatric disorder. It should also be noted that the Gove and Herb review was without the benefit of Maccoby and Jacklin's (1974) encyclopedic coverage of the psychology of sex differences and its subsequent critique by Block (1976, 1978). Hence, it is the purpose of the present review to extend Gove and Herb's earlier review in the hope of remediating its limitation.

In the absence of a generally accepted taxonomy (Achenbach & Edelbrock, 1978), the categories of child behavior disorders to be reviewed are those that have a special relevance to the issue of continuity between child and adult psychopathology (Kohlberg, LaCrosse, & Ricks, 1972; Rutter, 1972b). Childhood is considered as that period of the life span from birth to adolescence. The reason for this demarcation is that since adolescent sex differences in psychopathology closely resemble adult sex differences (Gove & Herb, 1974; Graham & Rutter, 1977; Rutter, 1974), it is the period prior to adolescence that requires attention. The findings, in accordance with Dohrenwend and Dohrenwend's suggestion, are analyzed not only in terms of the different experiences of the sexes but also in terms of the sexes' different endowments. These findings are then compared with those of the adult literature.

Finally, it should be noted that although expository convenience dictates a consideration of factors influencing sex differences under the separate rubrics of endowment or experience, in no way does the author construe these influences as polarized. Sex differences are construed here, as they are by virtually all theorists, to be multidetermined products of an interaction between biological and learning processes. This interaction has been variously considered by behavioral geneticists in terms of *norm of reaction* (McClearn & DeFries, 1973), by psychopathologists in terms of *diathesis–stress* (Rosenthal, 1970), by developmentalists in terms of a *greater readiness to learn* (Maccoby & Jacklin, 1974) and by psychosexual developmentalists in terms of an *imprimatur* (Money & Ehrhardt, 1972) that is shaped by a *social script* (Gagnon & Simon, 1973). The aptness of each

---

metaphor varies with the idiomatic conventions of one's discipline, and it is left to the reader to decide which if any of the images is the most suitable.

Methodological Problems

The methodological problems in making a diagnosis of psychological disorder in epidemiological studies of adult populations have been cogently detailed by Dohrenwend and Dohrenwend (1974). These same problems obviously exist in similar studies of child populations, as Conger and Cole (1975) noted in a recent example. Although it is beyond the scope of this review to engage in a detailed analysis of these problems, there is a major difficulty that must be considered.

In their review of the adult literature Dohrenwend and Dohrenwend scored the inadequacy of studies based on treated rates. Hence their review focused for the most part on studies of untreated cases of psychopathology, of which they uncovered 70 done since the turn of the century. This same problem of focusing on treated rates exists in the studies of child psychopathology, but unfortunately the paucity of studies of untreated cases renders similar recourse impossible. For example, Gove and Herb (1974) relied exclusively on treated cases, while noting that scattered results for studies of non-clinic-attending populations were generally consistent with their formulations.

Although the scarcity of prevalence studies of untreated psychological disorders in children makes any conclusions about sex differences somewhat tenuous, it does not render such an attempt futile. Rather, following the lead of Gove and Herb, such studies can be employed in a supportive fashion to confirm or disconfirm findings based on treated cases. Furthermore, there is the comforting finding of past researchers that prevalence rates based on untreated cases generally confirm the sex differences established by the data based on treated cases (Anthony, 1970; Gove & Herb, 1974). Hence, although the data base used to investigate the existence of sex differences in child psychological disorders is limited in comparison with that of the adult literature, it seems sufficiently robust to warrant such an examination.

Adjustment Reaction of Childhood

The most common child diagnosis is that of adjustment reaction of childhood (Anthony, 1970). The determination of the diagnosis can include virtually any symptom or set of symptoms that appear to be precipitated by acute situational stress.

In this regard it is interesting to note the general agreement among reviewers (Kanner, 1960; Kohlberg et al., 1972; Rutter, 1972b) that there is little continuity between these characteristics and adult psychopathology. Hence, the most common interpretation given to these symptoms is that they represent manifestations of developmental stress occurring in essentially well-adjusted children.

Studies of both treated and untreated cases of adjustment reaction of childhood indicate greater prevalence among males than among females (Anthony, 1970; Gove & Herb, 1974). However, this greater prevalence does not manifest itself until the school-age years (Richman, Stevenson, & Graham, 1975). The typical explanation given for this disparity is the greater stress on males due to their biological immaturity, their temperament, expectations for their behavior, and the feminine environment in which they live (Bardwick, 1971; Gove & Herb, 1974). Thus Bardwick maintained that cultural pressure on girls is much less because their general predispositions and the cultural interpretations of what is acceptable are more nearly matched. This lesser pressure enables a girl to experience a less stormy childhood. Examples of greater cultural pressure cited by Bardwick are the greater expectations for the male to achieve; the greater censure of the male who is passive, withdrawn, and overdependent; and the message given the male to be active and aggressive and, at the same time, the threat of punishment when these actions result in nonconformity. Gove and Herb added that this greater cultural pressure impacts on a male who is less intellectually and physically mature and more

aggressive, thus engendering even greater stress.

It should be noted that at the time these hypotheses were offered, research substantiation was minimal. More recently, however, empirical support for some of them has been accumulating. For example, Rutter (1977b) concluded his review of the literature on temperament by stating that there is good evidence individual differences in this variable play an important role in the development of psychological problems. He scored the following type of child as being especially at risk: a child who is emotionally tense, who is slow to adapt to new situations, whose behavior is difficult to change, who has irregular eating, sleeping, and bowel habits, who tends to be irritable and negative in mood, and who is unusually tolerant of messiness and disorder. Though Rutter himself did not mention sex differences, Moss (1974) summarized 10 years of his work with infants, consisting of several independent studies, and concluded that males were generally more irritable than females. This conclusion was confirmed in a recent study by Phillips, King, and DuBois (1978) on newborns that controlled for the methodological limitations of prior studies, not the least of which was the variable of male circumcision. Thus it seems that at least one of the temperamental attributes listed by Rutter shows a sex difference.

Another example is in the area of differential pressure for achievement. In a recent review Hoffman (1977) indicated that although boys and girls are both encouraged to do well in school, some important sex differences in achievement pressures may exist. She cited observational and interview studies in which parental interactions with sons emphasized greater achievement and competition than did interactions with daughters. Parents are also more likely to want their sons to be hardworking and ambitious and are more disappointed if they do not achieve their academic and occupational goals.

Other research pertinent to the traditional explanations are taken up later. At this juncture, however, there are two other explanations that have generally been overlooked in the literature but that merit equal consideration in the delineation of the divergent endowments and experiences of the sexes.

The first is simply that the annoyance threshold for male deviance is less than that for female deviance. For example, Shepard, Oppenheim, and Mitchell (1966), in a study that compared 50 referrals with matching nonreferral controls, concluded that it was primarily parental reaction, not severity of disturbance, that dictated a clinical referral. It appeared that clinic-attending mothers felt more puzzled and hopeless in coping with their children's problems than did control mothers. They further reported that the most obvious difference lay in the number of nonclinic mothers who accepted their children's behavior as a temporary difficulty and that this increased tolerance was particularly obvious among the mothers of girls. Similarly, Chess and Thomas (1972), in their study of temperamental differences in children, indicated that parents were less tolerant of a lack of persistence and of distractibility in males than in females. Battle and Lacey (1972), in a study of hyperactivity in 74 subjects drawn from the Fels longitudinal study, reported that mothers of highly active males were critical, disapproving, unaffectionate, and severe in their punishment. No correlation of these maternal behaviors with high activity levels in females was found. Serbin and O'Leary (1975) observed teacher-child interaction in 15 preschool classrooms. They reported that a disruption by a male was more likely to elicit a reprimand than a similar disruption by a female; males' reprimands were also more severe. For example, teachers responded over three times as often to males who hit or broke things, and the boys usually got a loud public reprimand.

Hence, it may be that females—mothers and teachers—are more likely to view the same disturbance as more pathological in the male than in the female. And since they are the primary sources of referral and evaluation in epidemiological studies, there is the resultant excess of males with adjustment problems. This may be partly a function of the fact that adults feel less comfortable and competent with children of the opposite

sex (Sullivan, 1953). Hence it is not surprising that in a national survey, Hoffman (1977) indicated that some of the most common reasons women gave for preferring a female were "that girls are easier to raise and more obedient . . . are cuter, sweeter, or not as mean" (p. 648).

This explanation, though, should be tempered by the caveat that one is assuming the disturbances are indeed the same. Although this assumption seems reasonable in the studies of Chess and Thomas, Battle and Lacey, and Serbin and O'Leary, since the authors themselves clearly designated the behaviors as similar, it would be rash to extrapolate these findings of similarity to the multitude of adjustment problems that the sexes present. For example, both Garai and Scheinfeld (1968) and Feshbach (1970) indicated that aggression in girls is more likely to assume a prosocial mode, for example, rule enforcement, whereas male aggression is more likely to be destructive. Hence the "same" aggression is less tolerated in males because it is actually dissimilar in mode. Though Maccoby and Jacklin (1974) challenged the validity of this distinction, it still serves the function of illustrating the slipperiness of designating similarity.

A second reason for the greater prevalence of male adjustment reactions of childhood relates to a difference in endowment, namely, that males may be constitutionally more vulnerable not only to biological but to psychological stress as well. As the reviews by Garai and Scheinfeld, Maccoby and Jacklin, and Birns (1976) indicate, there is little doubt that despite the fact that males are larger and stronger than females at almost every age, they are more vulnerable to almost any kind of physical hazard; and this vulnerability is magnified by the effect of poverty (Birns, 1976). Though the ratio of male to female conceptions is 130:100, the ratio is reduced to 105:100 at birth in the United States. They suffer more abortions, stillbirths, miscarriages, prematurity, anoxia, and other birth complications. They are also more likely than females to suffer serious defects as a result of prematurity (Braine, Heimer, Wortis, & Freedman, 1966) or anoxia (Gottfried, 1973). During infancy 37% more males die, and throughout life males are more afflicted by the major diseases (Garai & Scheinfeld, 1968). They are also more likely to suffer ill effects from malnutrition (Tanner, 1970) and radiation (Rutter, 1972b).

The reasons commonly cited for this greater male vulnerability are greater male immaturity (Rutter, 1972b), greater male susceptibility to sex-linked diseases (Garai & Scheinfeld, 1968), and possible adverse maternal immunological reaction to male fetal tissue because of the presence of the male Y chromosome (Mussen, Conger, & Kagan, 1974). Analogously, there appears to be a greater male vulnerability to psychological stress.

Rutter (1970) conducted a study of 200 families and matching controls in which one of the parents was a psychiatric patient. The sample contained an equal number of male and female psychiatric patients who had one or more children under the age of 15. Information about the families was obtained by psychiatric interview of the parents, and information about the children's psychiatric state was obtained by teacher questionnaire. He found that discord and disruption in the home was consistently and strongly associated with anitsocial disorder in boys but not in girls. No consistent associations were found between family characteristics and neurosis in either boys or girls. Nor did the sex of the ill parent bear a relation to the likelihood of the children's developing a psychiatric disorder. He then in some detail considered and dismissed the following possible methodological biases as alternate explanations to this provocative sex difference in preadolescent children: The sex difference is peculiar to the children's behavior at school; teachers cannot perceive deviance in girls as well as in boys; and the sex difference is due to diagnostic differences. By reviewing other relevant studies he concluded and found that though the evidence is surprisingly meagre and to some extent contradictory when considered in relation to his clear-cut findings, it indeed appears that males are more vulner-

able to adverse effects of family discord and disruption.

Similarly, Wolkind and Rutter (1973) in their Isle of Wight survey reported that there was a strong tendency for children who were in short-term (6 months or less) care because of maternal confinement or physical illness to have a behavioral disturbance, as defined by teacher and parent interviews. The tendency was much more marked for boys than for girls. With long-term care, howevers, girls seem to be as susceptible to ill effects as are boys. Rutter (1972a), in his review of the literature on maternal deprivation, pointed out that the findings on sex differences are somewhat contradictory and that no differences have been found in many studies. However, where there has been a difference, the male has usually been found to be more vulnerable to the adverse effects of separation. Bowlby (1973) cited a finding parallel to Rutter's in his review of the literature on separation anxiety. He reviewed five studies in which three found no sex differences and two found that males evidence greater separation anxiety than females. In the most comprehensive review to date, Maccoby and Jacklin (1974) reached a similar conclusion. In several studies of children aged 10 months to 3 years, males exhibited greater resistance to separation, as indicated by greater distress at separation or greater likelihood of quickly following the departed figure. More recently Waters (1978) reported that the normative data for the Ainsworth "strange situation" indicated that crying and its correlates were greater in males than in females in the second separation and reunion sequence at the ages of 12 months and 18 months.

A group of studies that are cognate to the studies on separation and deprivation are the studies of adoptive children. This kinship resides in the fact that adoptive children experience a break in the continuity of care prior to placement and frequently come from deprived backgrounds (Hersov, 1977a). In an extensive review of this literature, Hersov concluded that these and other stresses result in adoptive children's being at greater risk for the development of a psychiatric disorder. Furthermore, in those few studies that have employed a control group, males have been found to be more at risk than females.

Further indication of greater male vulnerability to environmental stress is found in the cognitive realm. Bayley (1970) conducted a review on the association of parental variables such as warm, hostility, restrictiveness, and so on with IQ. She concluded that there were clear indications that the mental abilities of males are more strongly related than those of females, both positively and negatively, to the emotional aspects of their environment. She also noted that there were indications that early experiences are more likely to have long-lasting effects on boys than on girls. Similarly, in two separate reviews and a recent study, maternal employment has been found to have a negative effect on male academic achievement (Etaugh, 1974; Gold & Andres, 1978; Hoffman, 1974). And finally, in a literature review on the effects of father absence on children's cognitive development, Shinn (1978), although concluding that the proportion of studies that found negative effects was the same for males and females, noted that three studies found stronger negative effects for males.

Recented, however, Kamin (1978) reexamined Bayley's data and concluded that no significant sex difference in susceptibility of IQ to environmental influence has been demonstrated. Furthermore, he contended that the differences in male and female samples with regard to maternal education and children's IQ variance confound whatever sex difference may be detected. Thus, for the present, it appears that the significance of Bayley's findings has been attenuated.

Perhaps the most interesting aspect of the above finding is that it dovetails so nicely with the undisputed fact of greater male vulnerability to biological stressors. Hence one is tempted to posit a correspondingly greater constitutional vulnerability to psychological stressors. The data, though far less decisive than they are for biological stress, do offer some intriguing support for this hypothesis. For example, it may be that the same psychological stress is more severe for males than for females simply because it

interacts with a less mature organism. It may also be that just as the female organism is more stable for physical and mental growth (Mussen et al., 1974), so it is more stable in maintaining psychological stability.

However, there exist equally plausible explanations for the seemingly greater male vulnerability to psychological stress. For example, in the case of familial stress, what is apparently the same situation may in practice be different depending on the sex of the child. Thus it may be that the male child for some reason has more contact with the disturbed parent, has more responsibility for the home when the parent is ill and so on. Though this hypothesis was tested and found wanting by Rutter (1970), it has not yet been adequately explored. It may also be that boys and girls respond to different family stresses. For example, Hoffman (1974) noted that in most child developmental studies girls show ill effects from too much supervision or control, whereas boys typically suffer from too little. Further, if one examines the studies indicating greater male vulnerability to psychological stress, it seems that lack of control rather than too much control more correctly typifies the family situation. Hence, it may be that in future studies that examine a greater range of stress variables, females may prove to be more vulnerable than males to some of them.

Parenthetically, it should be noted that the reasons for differential effect of under- and overcontrol are not clear. Though it would be convenient to evoke the hypothesis of differential socialization of the sexes, Maccoby and Jacklin (1974) concluded that the data reveal a remarkable uniformity in the socialization of the sexes. This has been challenged by Block (1978) and Hoffman (1977), largely on the basis of more recent research, none of which addressed itself directly to the point at hand. One can only note that this finding has an interesting parallel in the clear sex difference in adult psychopathology, in which there exists greater male prevalence of disorders of undercontrol, that is, personality disorders, and a greater female prevalence of disorders of overcontrol, that is, neurotic disorders (Dohrenwend & Dohrenwend, 1974).

Learning Difficulty

There is a male preponderance in all disorders that involve a specific delay in development (i.e., speech or language delay, nocturnal enuresis, and clumsy child syndrome; Rutter, 1977a). This preponderance continues into the school years; Kessler (1966) noted that academic difficulty is the reason for referral of at least three fourths of the children between the ages of 7 and 14 and that it is indisputably a male problem. Whether one looks at mental retardation (Lehrke, 1972, 1978), reading difficulty (Rutter & Yule, 1977), hyperactivity (Cantwell, 1977), or simply lower grades (Maccoby & Jacklin, 1974), males predominate. Given the seriousness of this problem in its portent for future adult maladjustment (Kohlberg et al., 1972), an examination of its possible causes becomes of major significance.

The causes cited by Gove and Herb (1974) were the slower intellectual and physical development of the male and the incongruity of establishing a male identity in the feminine world of the school. Again it seems that the endowments and experiences of the sexes are more divergent than the causes noted by Gove and Herb.

The feminine culture theory of male learning difficulty, although confidently put forth by Gove and Herb as well as others, requires closer scrutiny as to exactly how it operates. For example, sex of teacher per se does not seem to be the prime factor, since a review of eight studies found no notable favorable effects of male teachers on male students (Good & Brophy, 1977). That male teachers have little, if any, differential influence on male achievement is explained by the fact that male teachers interact with boys and girls in the same general way that female teachers do (Good & Brophy, 1977).

More relevant feminizing factors than the sex of the teacher seem to be either what is studied or the cultural stereotype toward learning in general. For example, Good and Brophy reported two studies in which the sex

difference in reading was eliminated when males read material of high interest to them. Also, Johnson (1976) surmised that one reason why the sex difference in reading is not evident in cultures such as those of Nigeria, Germany, and England is that reading in these cultures is deemed a masculine activity. Furthermore, to the extent that these and other factors are operative, they seem to affect the grades teachers award to males more than they affect actual achievement. Thus Garai and Scheinfeld (1968), in their review of sex differences in intellectual performance, indicated that females in elementary and high school are generally awarded higher grades than males despite the fact that males achieve as well as or, in some cases, better than females.

Though these environmental factors undoubtedly account for part of the observed sex difference in some learning difficulties, there are some equally compelling biological factors stemming from the dimorphism of the sexes that play a significant role. The first and most obvious biological difference, which Gove and Herb (1974) mentioned, is that the male child at school age lags approximately 1 year behind the female in physical maturation (Garai & Scheinfeld, 1968). Tanner (1970) hypothesized that the male maturational lag is probably due, indirectly, to the action of the genes on the Y chromosome. Thus, children with the abnormal chromosome constitution XXY (Klinefelter's syndrome) have a skeletal maturity indistinguishable from that of the normal male, and children with the chromosome constitution XO (Turner's syndrome) have a skeletal maturity approximating that of the normal female XX constitution.

This greater female maturation appears to be paralleled by a greater intellectual maturation. Bayley (1956) indicated that physical growth, as measured by height and skeletal maturity, is positively correlated with IQ scores. Note, however, that in individual cases physical growth, as measured by percentage of mature height achieved, is not correlated with IQ measured in terms of percentage of 21-year-old intelligence scores achieved. Parenthetically it should be added here that Maccoby and Jacklin (1974) cited Bayley to caution against the acceptance of a correlation between maturation and intellectual growth. However, as Bayley clearly indicated, this lack of correlation pertains only to individuals and not to groups differing in maturation. Thus, Sherman (1978) aptly pointed out that though physical growth spurt might not correlate with mental growth spurt within individuals, groups could differ, with both the physical and the mental growth spurts coming earlier in females. Tanner, (1970, 1978), in his review of the relationship between physical maturation and mental ability, stated that the more physically mature scored higher on mental tests in North American and European populations at all ages tested, going back as far as 6½ years. He thus concluded that in age-linked examinations more physically mature children have a significantly better chance than less mature children.

At present there seems to be general agreement with Sherman's cautious statement that there is no easy resolution to the question of whether the sexes differ in cognitive maturation. Though, as she added, it would be unwise to ignore this possibility. This caveat seems to be well-founded and should be most heeded when one considers young children. For example, Maccoby and Jacklin (1974) noted that when sex differences are found in general intellectual abilities between the ages 2–7 years, these differences usually favor girls. Furthermore, Block (1976) pointed out that their caution in interpreting this finding as being due largely to the disadvantaged origin of the samples is unjustified.

Hence, it comes as no great revelation to find Anthony (1970) stating that in the first grade boys are referred for help 11 times as often as girls for social and emotional immaturity, a syndrome characterized by a high rate of absenteeism, fatigue, inability to attend and concentrate, shyness, poor motivation for work, inability to follow directions, slow learning, infantile speech patterns, and problems in the visual–motor and visual perception areas.

The second obvious biological difference, which has been discussed before, is the

greater male vulnerability to a host of pre-, peri-, and postnatal stresses resulting in brain dysfunction (Birns, 1976; Garai & Scheinfeld, 1968; Maccoby & Jacklin, 1974). Furthermore, the role of brain dysfunction in learning disturbance seems well established (Heincke, 1972; Rourke, 1975), though the precise nature of the dysfunction is vigorously disputed (Vellutino, 1977). Hence, one of the sequelae of the greater male vulnerability to biological stress is the greater prevalence of males who are predisposed to learning disorders.

The third more controversial biological difference is that of greater male variability. Shields (1975) in tracing the evolution of the concept noted that one of its first serious discussants was Darwin, who used it to explain how in many species males developed greatly modified sexual characteristics, whereas females did not. This principle was next brought to the attention of psychologists by Ellis (cited in Shields, 1975), who extended it to mental abilities as well as physical traits. After noting that there were more men than women in homes for the mentally deficient, which indicated a higher incidence of retardation among males, and that there were more men than women on the rolls of the eminent, which indicated a higher prevalence of genius among males, he concluded that greater male variability probably held for all qualities of character and ability. A current application of this principle to mental ability comes from Lehrke's (1972, 1978) X-linkage theory of intellectual traits.

Lehrke (1972, 1978), along with his predecessor Ellis, maintained that males are more frequently represented at the extremes of the range of general intelligence. He further proposed that this greater male variability is best explained by assuming that there are major genes for intelligence on the X chromosome. Concerning the first hypothesis of greater male variability at the extremes of intelligence, Lehrke's own review of the literature, along with an independent review of 27 community epidemiological surveys by Abramowicz and Richardson (1975), indicated a greater prevalence of male retardates in both institutions and communities, spread out in time over 80 years and in space from Australia to Scandinavia. His response to the criticism of sex bias in diagnosis as an explanation was as follows: First, he contended that if there is a bias, it is in the opposite direction, since retarded females are institutionalized more frequently as a means of controlling their fertility. Second, he maintained that it is hardly plausible that all the studies showed the same type of sex bias in determining which individuals were counted as retarded; and even if some such bias were present, he contended that it is hardly conceivable that it would result in such extreme levels as to account for the difference seen in most studies (e.g., as much as a 76% male excess in some studies).

However, he noted that those studies showing the greater numbers of retarded males may mean merely that there is a greater amount of pathology affecting males' intellectual functioning, unless it can also be shown that there are more males at the high end of the distribution of IQs and that the greater prevalence of males at the low end follows a sex-linked pattern of inheritance. Since the contention of a greater male prevalence is both seriously questioned (Maccoby & Jacklin, 1974; Sherman, 1978) and tangential to the present discussion, it is the evidence for the sex-linked pattern that is examined.

The most persuasive support for this linkage comes from the findings that retarded women married to normal men are twice as likely to have retarded offspring as retarded men married to normal women and that there is a marked excess of families with male-only retardates. Anastasi (1972) criticized these supporting data by suggesting that since women have more of a role in child rearing, retardation should have a more debilitating effect on their offspring than should the retardation of their husbands. The force of this criticism became blunted, however, when Lehrke noted that this social deprivation hypothesis applies mainly to mild retardation and can hardly explain a fivefold increase in severely retarded children born to retarded mothers as compared with retarded fathers. Furthermore, this criticism, along with the criticism that the major factor may be ma-

ternal prenatal rather than maternal gene influences on the X chromosome, fails to account for the strong tendency of male retardation to run in families and of which the most likely explanation is an X linkage. And finally, in a sample of 5,049 pairs of individuals, Freire-Maia, Freire-Maia, and Morton (1974) examined three alternate explanations of what they referred to as an established sex difference in retardation. They concluded that a sex-modified threshold for mental retardation that includes sex-linked genes is more consistent with the evidence than hypotheses that stress either prenatal environmental or postnatal maternal socialization.

Psychosexual Disorders

Davison and Neale (1978) indicated that in Diagnostic and Standard Manual III *sexual deviations* will probably become *psychosexual disorders* and be divided into three categories in which only the gender identity or role disorder category (e.g., transvestism and transsexualism) will be pertinent to a discussion of childhood disorders. The two other categories of paraphilias (e.g., fetishism and rape) and psychosexual dysfunctions (e.g., impotence and dyspareunia) are the province of adult psychopathology.

In an adult population males exceed females in disorders of gender identity (Green, 1974; Pauly, 1974); and though studies of this disorder in childhood are just beginning, what research does exist points to a similar greater male prevalence among children (Green, 1974). In childhood this disorder takes the form of a cross-gender identification on such dimensions as self-concept, playthings, clothing preference, playmate preference, and so on (Green, 1974). Although research on the significance of this behavior for females is virtually nonexistent, three follow-up studies on males have documented the continuity of this behavior into adulthood. Out of a total sample of 27, 15 became adult transsexuals, transvestites, or homosexuals (Green, 1977).

Two theories have been offered to explain this greater male prevalence. A psychoanalytically oriented theory of identification proposes that gender differentiation is more difficult for the male. For although both sexes initially identify with the mother, it is only the male who has to switch this identification (Green, 1974). Consequently, this additional hurdle entails the concomitant greater probability that male gender differentiation will not be successful.

A biologically based theory proposes that there is a prenatal hormonal hurdle that only the male has to surmount (Green, 1974): that is, as Money (1974) has indicated, it appears that nature's rule is that to masculinize something must be added. Specifically, at about the 6th week of prenatal development, masculinizing substances must be released by the fetal testis for morphologic differentiation of males, whereas no sex hormone whatsoever is necessary for the differentiation of morphologic females. Thus, if both embryonic gonads are removed prior to the critical period when the sexual anatomy is formed, then the embryo will proceed to differentiate as a morphologic female, regardless of genetic sex. Of these two masculinizing substances, one, known only by its function, is the müllerian inhibiting substance. Without it the male is born with the müllerian ducts differentiated into a uterus and fallopian tubes, as in the female. The other substance is androgen, the male sex hormone, essential for differentiation of the internal masculine reproductive tract and for the differentiation of the external sexual anlagen into male structures instead of their female homologues—that is, the clitoris, clitoral hood plus labia minora, and labia majora, instead of, respectively, the penis, penile skin covering, and scrotum. This release of fetal hormones results not only in the aforementioned genital dimorphism but also in a brain dimorphism, the significance of which is discussed later. Parenthetically, it should be mentioned that even in the last stages of differentiation in puberty, the changes of males are more striking and extensive than those of females (Tanner, 1978).

Thus, in a dual system in which the female path automatically evolves and the alternate male path requires specific influences at spe-

cific intervals, more errors probably occur along the latter path. This greater probability of error is theorized to contribute to the greater prevalence of male gender identity disorders.

Antisocial Behavior

In their review Kohlberg et al. (1972) stated that antisocial behavior, particularly when some estimate of severity is taken into account, is the single most powerful predictor of adult maladjustment. Hence the decisive male preponderance in aggressive behavior, which is probably the most unequivocal sex difference in the literature (Feshbach, 1970; Hoffman, 1977; Maccoby & Jacklin, 1974; Terman & Tyler, 1954), takes on a special significance. Furthermore, this difference, as Maccoby and Jacklin concluded, is real and cannot be explained away by simply positing different modes of expressing aggression (Feshbach, 1970). However this should not be construed to mean that women are always less aggressive than men (Frodi, Macaulay, & Thome, 1977). This preponderance in aggressive behavior manifests itself in males' exceeding females in both delinquent and nondelinquent disturbances of conduct (Wolff, 1977) and in externalizing symptoms in general (Anthony, 1970). This ratio persists into adulthood, where males predominate in personality disorders (Dohrenwend & Dohrenwend, 1969, 1974).

The most common explanation given for this disparity is differential socialization. Mead (1949) provided some of the most dramatic data for this explanation with her findings of sex role reversal among the Tchambuli, in which the females were the aggressive, dominating personalities. Parenthetically, it should be noted that the reversal was not complete, since it is the men who fight when the Tchambuli go to war (Brown, 1965). Since then authors, following the lead of Sears, Maccoby, and Levin's (1957) finding that parents make the greatest distinction between child rearing of boys and girls in the area of aggression, have attempted to investigate the nuances of this socialization process. Reviews on sex role acquisition by Mischel (1966), Mussen (1969), Feshbach (1970), Bardwick (1971), and Maccoby and Jacklin (1974), just to name a few, typically mention learning mechanisms such as operant conditioning, modeling, and frustration aggression as mediators of the socialization process. On the basis of these and numerous other reviews, further slaying of the Freudian myth of innate female passivity would be tedious overkill; and one can safely assume that differential socialization is a major factor in explaining the sex differences in antisocial behavior.

As with many myths, however, there resides an element of truth; and it is likely that differential socialization is not the complete explanation. Most authors have recognized this. For example, Feshbach (1970), in his exhaustive review of childhood aggression, wondered "whether from a biosocial view, it is also reasonable to ask whether it is easier to facilitate aggressive behaviors in boys than in girls and what the implications of this training might be for other behaviors of the child" (p. 189). In view of current research, it might be added that it would be unreasonable to assume otherwise. In the most extensive review to date, Maccoby and Jacklin (1974) concluded that the higher level of male aggression probably cannot be completely explained by a learned fear of aggression among girls, by any tendency for girls to reinforce the aggression of boys, or by the tendency of adults to reinforce aggression more in males. This conclusion regarding the socialization of aggression is part and parcel of Maccoby and Jacklin's overall conclusion that parental socialization data show little differences between the sexes. And although this surprising and controversial interpretation has been seriously questioned (Block, 1978), the conclusion that differential socialization is not an exhaustive explanation of the sex difference in aggression seems secure, as the following discussion soon indicates. Maccoby and Jacklin contended that the male's greater aggression has a biological component. This biological disposition to greater aggression stems not only from the greater mesomorphy of the male,

which is manifested by age 5 (Willerman, 1979), but also from the effects of the male hormone on the organism.

The correlation between mesomorphy and variables such as aggression and delinquency is clearly established whether one interprets this correlation as a manifestation of the same underlying biological structure or as the influence that different constitutions have on the successful reinforcement of instrumental responses (Feshbach, 1970; Hall & Lindzey, 1973; Shah & Roth, 1974). This predisposition to aggression because of greater psysical strength is further reflected in the fact that there is no society on record in which the female does the actual fighting in warfare (Brown, 1965).

The second factor predisposing the male to greater aggressivity is the male hormone, androgen, whose importance has been dramatically demonstrated in animal research. Reviews by Money and Ehrhardt (1972), Hart (1974), Quadagno, Briscoe, and Quadagno (1977), Reinisch and Karow (1977), and Vandenberg (1978) indicate that whereas the male of the vertebrate species is the more aggressive in both laboratory and natural situations, the administration of the male hormone either pre- or postnatally results in the female's being equally aggressive.

Something analogous to this also occurs in humans. Block (1976) disagreed with Maccoby and Jacklin's (1974) verdict of no sex differences in activity level. She pointed out that not only have they erred in their interpretation of some of the studies but they have also omitted nine relevant studies, all of which reported a higher male activity level. In addition, a recent epidemiological investigation of 705 3-year-olds randomly sampled from the community reported that although the overall prevalence of behavior problems did not differ for the sexes, males did exceed females in being described as too active (Richman et al., 1975). Furthermore, Willerman (1979) indicated that mortality figures among children aged 1–4 years show that boys are much more likely than girls to die from accidents and that many of these differences are clearly present around age 1. Although acknowledging the possibility of differential child-rearing practices, he concluded, and is supported in this conclusion by Maccoby (1976), that there are only weak indications that parents may be less watchful of boys than girls in the early years. Hence, even though Fagot (1978) has recently reported that in children aged 20–24 months, males are more likely to be left alone by their parents, it seems that Willerman is still correct in concluding that boys are more likely to have a higher activity level than are girls.

Hence, a higher male activity level (which serves as a precursor to a higher aggression level [Patterson, Littman, & Bricker, 1967]) seems to be an established sex difference. Furthermore, Quadagno et al.'s recent review of the research on fetally androgenized human females supports Maccoby and Jacklin's contention that the consistency of findings with animal experimental work of a higher activity level among females is especially compelling in establishing a biological base for this difference.

This parallel with the animal research is all the more convincing in light of the excessive caution that Maccoby and Jacklin attached to attributing too much significance to this analogue. They, along with Quadagno et al., suggested that the cortisone therapy that the females received may account for their higher activity level. However, this caution is rendered less persuasive when it is noted that the females whose syndrome was progestin induced did not receive such treatment and yet manifested the higher activity levels. Furthermore, similar investigations of boys with either the adrenogenital or progestin-induced syndromes reveals comparable increases in activity level (Brecher, 1971; Erhardt & Baker, 1975).

They also warned that since the results were based on parental report, the report may have been inaccurate or the parental perception of the females as more tomboyish may itself have induced the reported difference; but this also seems overly cautious. Reinisch and Karow (1977), in their review of the effects of prenatal exposure to synthetic estrogens and progestins on human development, concluded that it seems unlikely that

the fact a mother knew her child was treated had a significant effect on her treatment of that offspring. They indicated that different hormone treatments have been shown to have different effects, which is difficult to explain in terms of maternal caretaking.

There is additional evidence that maternal knowledge is not a significant factor in the common finding that mothers have no recall of their having taken the hormones. Even in the case in which the effects are a change in genital morphology, as in the oft quoted Erhardt and Money (1967) study, parental attitude toward the child and her behavior is difficut to predict. Erhardt (1973) noted that parents did not have a consistent attitude toward their masculinized daughter, when compared with control parents, that could explain the tomboy syndrome.

Neurosis

In contrast with children with antisocial symptoms, children with neurotic problems are almost as likely to be mentally healthy adults as a random sample of the population (Hersov, 1977b; Kohlberg et al., 1972; Rutter, 1972b). Also in marked contrast with the female preponderance in adult neurosis (Dohrenwend & Dohrenwend, 1969, 1974), males either equal or exceed females in childhood neurosis (Gilbert, 1957; Gove & Herb, 1974; Hersov, 1977b). It is not until adolescence that the adult ratio begins to manifest itself (Gove & Herb, 1974; Hersov, 1977b; Rutter, 1974; Terman & Tyler, 1954). Many of the reasons for this greater male prevalence seem to be similar to those already adduced for the greater male prevalence in childhood adjustment reactions and hence are not in need of further elaboration. Furthermore, with the additional explanation of adverse reactions secondary to the greater male prevalence of learning problems (Corbett, 1977; Rutter & Yule, 1977), it seems that the major interpretations have been explored. Hence, what remains is to examine the reasons for the difference between child and adult sex ratios.

Gove and Herb (1974) concisely summarized the explanations that rely on sex role theory. These explanations are evaluated in the light of more current research and complemented by explanations that have a more biological focus.

Gove and Herb sounded their familiar theme of differential stress and hypothesized that adolescence brings an increase of stress for females and a decrease for males. The feminine sex role is thought to become more stressful first because there is a sudden narrowing of the sex role, in that the female is restricted from engaging in activities that are then deemed too masculine. Such a precipitous constriction of sex role is thought to induce conflict and anxiety since these activities have most likely been integrated into her personality. The prime example given of this type of stress is that females who were once rewarded for academic success find, in adolescence, that they should not surpass men. Consequently, they come to fear success. In support of this hypothesis, Hoffman (1977) indicated that females, though no less achievement oriented than males, appear more attuned to the negative consequences of academic and occupational success. This concern reflects the realities of the situation, since for women—particularly during the adolescent and college years when heterosexual relations are salient—the rewards of high academic and occupational success are uncertain and their costs—often in the form of affiliative loss—real. However, if fear of success is assessed on a fantasy basis, there appears to be little overall sex difference (Tresemer, 1974; Zuckerman & Wheeler, 1975).

Second, females are hypothesized to perceive their roles as depending on the actions of others, and because of this they experience more uncertainty about the future. This hypothesis receives strong support from Douvan and Adelson's (1966) massive study of 3,500 adolescents in the 1950s. Both then and now, for a majority of females identification with a future adult role involves primarily that of wife and mother (Conger, 1977). As a result, Douvan and Adelson concluded that females' adolescent adaptation is more difficult because they face a more ambiguous task in adapting their present life and self-concept to the future. The ambi-

guity stems from the fact that marriage, unlike occupation, is less a matter of simple individual choice for females than for males and lies not in the immediate future but beyond in some relatively unspecified time. Marriage lends itself neither to rational planning nor to specific preparation, since it involves the decision and initiative of another person.

Furthermore, it seems that with the traditional feminine role in a state of transition, the assumption of a future feminine identity is becoming even more ambiguous. The alternate satisfactions of career achievement are often seen as incompatible with those of marriage and motherhood (Hoffman, 1977). As Conger suggested, this may mean that the female is exposed to conflicting social rewards and punishments no matter which role she assumes.

Third, because of their characteristic dependency, females are hypothesized to find the transition to an independent status, which starts in adolescence, more difficult. Though Maccoby and Jacklin (1974) have challenged this conventional notion of greater female dependency, other reviewers have reaffirmed its validity (Block, 1976; Hoffman, 1977). What appears to be disconfirmed, however, is the hypothesis that females find the transition to an independent status more stressful. Conger's review indicates that females appear to experience fewer and less stressful conflicts over the development of independence than do males, particularly in early adolescence. He indicated that males are more likely to be actively engaged in establishing independence from parental control, to be concerned with issues of self-esteem and achievement of responsibility for their own actions, and to be more preoccupied with issues of self-control (e.g., control of temper and impulsiveness).

It may be possible to reconcile these seemingly contradictory positions in two ways. First, it may be that Conger's (1977) findings are applicable to late adolescence. This possibility however, while tempting, remains speculative. A second possibility with more research support is that the two positions look at different manifestations of the same phenomenon. Rutter, Graham, Chadwick, and Yule (1976) examined the concept of adolescent turmoil in the context of findings from a total-population epidemiological study of Isle of Wight 14–15-year-olds. Though their findings do not directly relate to the independence issue, an extrapolation to this issue seems appropriate. The study concluded, along with American studies as summarized by Conger, that parent–child alienation is not a common feature unless adolescents have already showed psychiatric problems. In addition, the study supported Conger in finding that when alienation existed, it was more common among males. However, the study also concluded that inner turmoil as represented by feelings of misery and self-depreciation was quite frequent and more common among females. Thus it may be this manifestation of stress that Gove and Herb have alluded to.

The fourth and final hypothesis offered by Gove and Herb is that as adolescent females prepare for and start moving into adult roles they become aware that males are favored in our society and start experiencing the stress associated with their adult sex role. Though this hypothesis is offered more in the form of a confident assertion than as a result of well-based knowledge, a study by Peskin (1972) confirms its basic thrust. Using a sample of 31 male and 33 female subjects from the longitudinal Berkeley guidance study (cited in Peskin, 1972), he reported that for both sexes a change from a relatively tension-free or conflict-free preadolescence to a stressful adolescence is predictive of positive adult mental health. He further found that a greater number of these changes, for example, from high to low self-confidence, are predictive of positive adult mental health for females than for males. Peskin concluded that adolescence clearly appears more disquieting for the female, possibly because of her unique task of acquiring what psychoanalytically oriented theorists term a *self-assured passivity*.

In addition to these hypotheses, there are others that focus on two of the basic biological differences between the sexes, the internal and external sexual structures. These

dimorphisms tend to be construed by Freudian theorists in terms of biological imperatives with pervasive influences on psychosexual functioning. Other theorists propose that the reverse is likely to be true and that the sexual area may be precisely that realm in which the superordinate position of the sociocultural over the biological level is most convincing (Gagnon & Simon, 1973). It is the implications of this latter position that are sketched in detailing additional biologically based reasons for a more stressful female adolescence.

With the onset of female adolescence, there occurs the sexually dimorphic trait of a cyclic release of gonadotrophin, which results in, among other things, menstruation. Furthermore, it appears that for many women there are also attendant feelings of tension, irritability, anxiety, and depression, composing the syndrome of premenstrual tension (Bardwick, 1971; Conger, 1977). This syndrome has been found to be correlated with violence, death by accident and suicide, and admission to a hospital because of acute psychiatric disorder (Graham & Rutter, 1977; Moyer, 1973). Although it is not clear to what extent this syndrome can be attributed to actual physiological causes or to the script of a culturally induced expectation (Parlee, 1973; Ruble, 1977), it is commonly accepted that adverse emotional consequences are a corollary for at least some women (Graham & Rutter, 1977). And to the extent that this is so, it can be considered contributory to a more stressful female adolescence.

A second hypothesis focuses on the reactions of adolescents to the physical changes engendered by puberty. Conger (1977) reported that such changes cause more concern for females, with a substantial minority reporting feeling shame and anxiety over a change such as menstruation. This greater female concern is due in part to the fact that only the female has to face the possibility of an unwanted pregnancy. This possibility is the number one worry of parents of females (Hoffman, 1977) and is undoubtedly communicated to their daughters. Consequently, whereas the male has only to fear sexual failure, the female has to fear failure and success simultaneously (Gagnon & Simon, 1973). Hence it is not surprising that the most common reaction of females to the first experience of intercourse is fear, whereas for males it is excitement (Sorenson, 1973).

In addition, the physical changes with their dramatic effects on physical attractiveness are a further cause of the greater concern of females. Berscheid and Walster (1975) have amply documented the overriding importance of physical attractiveness in the adolescent dating situation, and this probably explains why physical attractiveness outweighs all other concerns in early adolescence (Eme & Goodale, in press). Furthermore, since female popularity is more closely related to physical attractiveness (Berscheid & Walster, 1975), it comes as no great revelation that physical attractiveness causes them more concern than it does males (Eme & Goodale, in press; Musa & Roach, 1973).

In sum, these hypotheses suggest that, beginning in adolescence, females tend to experience more stress than males. Moreover, they seem more disposed to respond to this stress according to the sex-stereotypic pattern of internalization rather than externalization (Achenbach, 1966; Anthony, 1970; Garai, 1970; Locksley & Douvan, Note 1), with the resultant greater prevalence of neurotic symptomatology.

These preceding hypotheses that suggest a more stressful female adolescence are complemented by others that suggest a lessening of stress in some areas for males. Gove and Herb (1974) indicated that males start performing better academically. This is attributed to a maturational "catch-up," the increasing importance of "masculine" subjects such as mathematics and science and the increased relevance of schooling to their long-range vocational goals. These hypotheses, like the previous ones, are evaluated in the light of more current research and are complemented by explanations that have a more biological focus.

The hypothesis of maturational catch-up receives support from the most extensive review to date on sex-related cognitive differences, that by Sherman (1978). She endorsed the generalization that though females are

generally verbally precocious compared with males, males eventually catch up, although females retain a slight edge in verbal functioning. She attributed this catch-up both to maturation and to the exposure of males to heavy educational intervention in verbal training.

In the area of mathematical skills, Sherman, along with Maccoby and Jacklin (1974), concluded that beginning in adolescence males tend to outperform females. She differed from Maccoby and Jacklin by placing the onset later in adolescence, by assessing the difference as nonexistent or minimal once previous mathematical background was controlled for, and by rejecting a biologically based male superiority in spatial ability as contributory to whatever male superiority did exist. However, reviews by Waber (1977) and Goleman (1978) have both affirmed the strong possibility of a biological basis for greater male spatial ability.

Despite the preceding disagreements, it does seem clear that whether one views male adolescent mathematical ability as greatly or minimally superior to that of females, it undoubtedly contributes to improving male academic performance. Also, there is sufficient support in the data for a biological basis for this ability, Sherman notwithstanding, and at the very least, a prudent person would not totally ignore this possibility, as did Gove and Herb (1974).

The increased relevance of schooling to the long-range goals of males needs to be closely scrutinized in light of the significant changes in the vocational orientation of females (Conger, 1977). Although this greater relevance was undoubtedly true some 20 years ago when the studies cited by Gove and Herb, such as that of Douvan and Adelson (1966), were actually conducted, there is a question as to its continuing validity. For example, in the most thorough study to date, Buxton (1973) surveyed 6,500 students in grades 7–12 in four separate school systems and reported that both sexes were highly concerned with the relation of schooling to the future. Moreover, females were found to deny disliking school more strongly than males and to like teachers more and to express more feelings of guilt and anxiety about school. Hence it may be that schooling does take on increased relevance for males, but this does not mean that it becomes less relevant for females. What may be true, however, is that despite the fact females are at least equally concerned about school as males, this concern does not have the same consequences for them. Thus, Locksley and Douvan (Note 1) reported that objective academic achievement was associated with less stress for adolescent males but not for females. Indeed, they found that females with high grade point averages were more depressed and reported more psychosomatic symptoms than males with high grade point averages, and they were not significantly less aggressive than females with low grade point averages. Locksley and Douvan suggested that the reason why actual academic achievement did not reduce stress in females is that grades constitute a basis for social comparison with peers, precipitating conflicts over standards of femininity and sexual desirability, and that the anticipated ramifications of academic achievement for future work and family plans are conflictful for females. To the extent that this is so, it reflects Garai's (1970) conclusion that for males happiness appears to be highly correlated with some strong vocational interest that manifests itself frequently during puberty or even earlier, whereas females are more interested in interpersonal relations. Consequently, though commitment to vocational goals, as signified by successful academic achievement, may serve to mitigate the stress of adolescence for males, for females such success may paradoxically precipitate even more stress.

Although the preceding discussion offers support for a decrement in stress in adolescence for males relative to females, there is other evidence that suggests that this decrement may be somewhat illusory. Because of the cultural proscription against male emotionality (Hoffman, 1977), males may learn to mask the neurotic expression of their problems in much the same way that Kagan and Moss (1962) have suggested they mask the expression of dependency. Toolan (1962) and Glaser (1967) have both indicated that

many of the acting-out symptoms of adolescents may camouflage underlying depression. This may explain why Achenbach and Edelbrock (1978), in one of the most sophisticated factor analytic studies to date of syndromes derived from parental report of clinic-attending children (aged 6–16 years), indicated that all samples except the 12- to 16-year-old male sample, yielded a factor labeled depression. It is not surprising, then, that Graham and Rutter (1977) indicated that whereas boys with disturbances of conduct are likely to be referred to a psychiatrist, when they get older these same personality disturbances or criminal behaviors are often likely to be dealt with in other ways. Thus the altered sex ratio in neurotic disorders that begins in adolescence and with it the implication of a less stressful male adolescence may be partly an artifact of a different manifestation of stress and the consequent referral process.

Furthermore, the increment in stress in adolescence for females, as indexed by greater "inner turmoil" (Rutter et al., 1976), may also be partly illusory. Garai (1970) suggested that the presence of anxiety or fear may not be a reliable indicator of mental disturbance for females. He noted that since they seem to live at a generally higher level of anxiety than males do, this may be a sign of alertness to danger and stress and may enable them to cope better with emergencies and endure anxiety and fear for longer periods of time than men, who tend to repress anxiety. Hence to a certain extent greater female inner turmoil may be adaptive rather than maladaptive.

In summary, whereas in childhood it seems that cultural pressures are more dissonant for male predispositions, in adolescence they are more dissonant for females. This dissonance can be expected to be coped with in sex-stereotyped patterns of internalization and externalization, with the correlative change in the sex ratio for neurotic disorders.

Psychosis

For a long time most writers tended to group all the psychoses of childhood together, usually under the term *schizophrenia of childhood*. However, in recent years the situation has changed radically, and there is a general (but not quite universal) recognition that the generic term *childhood schizophrenia* covers a number of quite different syndromes, which should be differentiated (Rutter, 1977c). The distinction that is most commonly made is between autism and childhood schizophrenia. This distinction has received impressive support (Rutter, 1978) and is embraced in this presentation for reasons that are detailed later. However, it should be noted that many, such as Bender (1971) and Miller (1974), reject this position; and in fact, the National Society for Autistic Children has adopted the official posture that to conceptualize autism as the earliest form of schizophrenia, which becomes manifested in later childhood or early adulthood, is equally valid. Though agreement on this distinction is lacking, there is enough specificity to at least distinguish nonpsychotic from psychotic children (Keith, Gunderson, Reifman, Buschbaum, & Mosher, 1976). In addition, there is agreement that whatever the syndromes of child psychosis may be, it is the most debilitating of all forms of psychopathology in the severity of its symptoms and the bleakness of its prognosis (Hintgen & Bryson, 1972; Rutter, 1977c).

With regard to autism, there seems to be universal agreement that males outnumber females in ratios ranging from 2:1 to 4:1 (Goldfarb, 1970; Hintgen & Bryson, 1972; Kanner, 1973; Rutter, 1978; Schopler, 1978). This ratio differs from that of adult schizophrenia, in which the sex ratio is the same (Dohrenwend & Dohrenwend, 1969, 1974; Rosenthal, 1970) and is one of the facts adduced to advance the contention that autism and adult schizophrenia are different nosological entities.

Although there is little agreement on the specific causes of autism, there is general agreement among those who have reviewed the research that when the etiology is eventually established, organic factors will be found to play a major role (Ornitz & Ritvo, 1976; Rutter, 1977c; Schopler, 1978). The one reviewer (Ward, 1970) who opted for an

etiology of primarily psychological factors seems to have been seriously deficient in his coverage of the literature (L'Abate, 1972; Rimland, 1972). As the most current reviews indicate, the majority of autistic children demonstrate severe deficits in intellectual, perceptual, and linguistic development (Friedman, 1974; Gunderson, Autry, & Mosher, 1974; Hintgen & Bryson, 1972; Rutter, 1977c; Rutter, 1978). Accordingly, it is currently thought that deficits in social behavior are less a cause than a reflection of dysfunction in other areas of development.

If one adopts this position, then it seems that the sex ratio can be explained largely in the same terms as were used to explain the similar sex ratio in learning difficulties. For example, one of the more tenable interpretations of childhood autism is that it is explicable primarily in terms of a language deficit, which in turn is rooted in defective cognitive functioning (Rutter, 1977c). This hypothesis is remarkably similar to Vellutino's (1977) conceptualization of dyslexia. In a comprehensive review, he rejected explanations based on visual perception, intersensory integration and temporal-order processing and concluded that the evidence most favors a verbal-deficit hypothesis.

One must add the caveat, however, that this analogy does limp quite noticeably, as Rutter (1968, 1974) pointed out. First, two of the most conspicuous contributors to learning difficulties, retardation and central nervous system dysfunction, are absent in fully one fourth to one third of autistic children. Second, the vast majority of children with learning difficulties do not manifest the symptoms common to autism. Furthermore, even though the learning difficulties concomitant with retardation characterize the majority of autistic children, it is clear that autism constitutes a syndrome that is different from that of retardation (Rutter, 1978; Schopler, 1978). Third, even where the analogy is most apt, as in the case of children with developmental, receptive-language disorders, autistic children differ in several important ways (Rutter, 1977c). Hence, until a more exotic kind of learning difficulty is discovered, the parallel, although currently considered the most plausible, remains imperfect.

As noted before, the greater male prevalence in autism stands in contrast with the parity of the sex ratio in adult psychosis and hence requires explanation. The most compelling explanation involves the medical model and posits different disease entities. The affective psychoses, which are virtually unheard of in childhood (Lefkowitz & Burton, 1978; Rutter, 1977c), are thought to have a strong biological base (Becker, 1977; Depue & Monroe, 1978; Gershon, Bunney, Leckman, Van Eerdewegh, & DeBauche, 1976) and this base may simply program a vulnerable organism for an adult rather than a childhood manifestation and for the resultant sex ratio.

Likewise, Rutter (1977c, 1978) made a strong case for autism's being a disease entity different from schizophrenia. He noted that autism differs from schizophrenia in terms of time of onset, social class, family history of schizophrenia, evidence of cerebral dysfunction, symptom patterns, level of intelligence, and course of the disorder. This distinction is further buttressed by the impressive evidence for genetic influences in schizophrenia (Cancro, 1976; DeFries & Plomin, 1978; Folstein & Rutter, 1977; Gottesman & Shields, 1976) in contrast with the minimal evidence for autism (Folstein & Rutter, 1977; Hanson & Gottesman, 1976). Thus, as with the affective psychoses, the sex differences in autism and schizophrenia can be most plausibly explained by positing different biological factors that result in different disease entities and hence in different sex ratios.

Although the preceding discussion has conceptualized autism and adult psychosis as distinct disease entities and has employed this distinction to explain the different sex ratios, mention was also made of the fact that a psychotic process similar to adult schizophrenia can manifest itself in childhood. This manifestation also involves a preponderance of males (Rutter, 1977c); but since it is conceptualized as being similar to adult schizophrenia, an explanation other

than one based on a biological difference is required.

The most plausible explanation stems from research on sex differences in the child and adolescent preschizophrenic personality. Both follow-back studies (Watt & Lubensky, 1976; Watt, Stolorow, Lubensky, & McClelland, 1970; Woerner, Pollack, Rogalski, Pollack & Klein, 1972) and preliminary findings of ongoing high-risk studies of schizophrenia (Mosher, Gunderson, & Buschbaum, 1972) indicate that whereas female preschizophrenics present a pattern of overinhibition, sensitivity, conformity, and introversion, males, in contrast, present patterns of unsocialized aggression. Hence it may be that because the unsocialized aggressive symptoms of males are more salient, their schizophrenia is more easily recognized, and therefore they are more likely to be diagnosed than female schizophrenics.

Summary and Conclusions

Recognizing the absence of a generally accepted taxonomy for use in diagnosing psychopathology in children, the present review chose to examine sex differences by focusing only on those categories relevant to the most important issue of continuity between child and adult psychiatric disorders. The review revealed a greater male prevalence in all of the following categories: adjustment reactions, antisocial disorders, gender identity disorders, learning disorders, neurotic disorders, and psychotic disorders. This finding stands in marked contrast with adult sex differences, which, beginning in adolescence, eventuate in a greater female prevalence in neurotic disorders and affective psychotic disorders, a greater male prevalence in personality and gender identity disorders, and no sex difference in schizophrenic disorders. The reasons for the childhood sex ratios and their lack of continuity into adulthood were examined in light of what is currently known about the differential endowment and experiences of the sexes.

This contrast between child and adult sex differences in psychopathology is perhaps the most salient finding to emerge from the review and suggests the two following conclusions. First, the validity of the contrast relies to a significant extent on the use of referrals rather than community surveys to arrive at the childhood sex differences. To the extent that this obviously limited source is validated in other ways, it seems apparent that the male child is more at risk for maladjustment than the female. Hence it would be wise for those engaged in primary prevention programs to take cognizance of this and address their efforts accordingly.

Second, though differential stress is clearly a major factor in explaining the contrast, it is equally clear that sex role per se is not the exclusive mediator of this stress. Biological factors play an important role and need to be given far more attention than they have been given in the recent past.

Heredity Versus Environment: An Integrative Analysis

Neil Gourlay
Department of Education
University of the Witwatersrand, Johannesburg, South Africa

Jencks's method of analysis of the heredity–environment data is presented, but with the important modification that cognizance is taken of the principle of genetic variation with age, that is, that the genotypic value (*G*) varies with age. As a result of this modification and a more critical examination of the original data on IQ, a solution is obtained that agrees with Jencks's figure for covariance, but supports the Burt–Jensen emphasis on heredity in that it assigns 75% of the remaining variance to heredity and only 25% to environment. The present study can be regarded as integrative in that (a) it eliminates most of the discrepancies in the field and (b) it uses Jencks's approach, albeit modified, to produce what is essentially Burt's result.

Of the many attempts at solving the problem of IQ heritability, probably the best known is that of the late Sir Cyril Burt. His claim that 75%–80% of IQ variance could be attributed to hereditary differences and only 20%–25% to environmental differences became general knowledge in the United Kingdom, with the publication of the article, "The Multifactorial Theory of Inheritance and its Application to Intelligence" (Burt & Howard, 1956). In the United States, however, Burt's work did not receive any marked degree of recognition until Jensen (1969) wrote in support of Burt's findings. Kamin (1974) aroused further interest in Burt 5 years later, but in this case it was the voice of criticism, directed mainly at Burt's handling of his data.

The solution that Jencks et al. (1972) offered in Appendix A of their book *Inequality* might be regarded as one of the strongest alternatives to that of Burt and Jensen. According to this solution, hereditary differences account for about 45%–50% of the total IQ variance and environmental differences for 30%–35%. The remaining variance (about 18%–19% of the total) is attributed to heredity–environment covariance, the concept that parents of good heredity not only pass on their superior genes to their children but also tend to provide them with superior intellectual environments.

In their 1956 article, Burt and Howard gave a figure of about 10% for covariance. But this was obtained for IQ group test data, and since they were primarily looking for data amenable to the application of Fisher's genetic theory (Fisher, 1918), they favored adjusted IQ assessments in which the attempt was made to eliminate systematic (i.e., between families) environmental effects. The result was the reduction of the covariance term virtually to zero. (It was this adjustment of IQs that became a main object of Kamin's criticism.)

Besides the efforts of Burt and Howard and Jencks et al., mention can be made of other approaches, such as multiple abstract variance analysis (MAVA; Cattell, 1960). Of particular importance is the work of two schools of biometrical genetics: the Birmingham school (Fulker, 1974; Jinks & Eaves, 1974; Jinks & Fulker, 1970) and the Hawaiian school (Rao, Morton, & Yee, 1974, 1976). Both these schools represent developments of the classical genetic theory laid down by Fisher (1918). The Birmingham school was influenced also by Mather (1949) and the Hawaiian school by Wright (1931). An important contribution of Wright was his development of path analysis, a technique that is used both by the Hawaiian school and by Jencks.

Requests for reprints should be sent to Neil Gourlay, who is now at the Department of Psychology, New University of Ulster, Coleraine, Londonderry, Northern Ireland BT52 1SA.

The essential difference between the two schools is their treatment of *dominance*, the concept that originated with Mendel, namely, that genes do not necessarily combine in a simple additive fashion at any one locus but can interact, thus adding to the genetic variance. (There is also the possibility of interaction between genes at different loci—what is known as *epistasis*.) Dominance is an important feature of the Birmingham school's approach to IQ heritability analysis. The Hawaiian school, on the other hand, chooses to exclude dominance from their genetic model, the argument being that it is more important to assess environmental effects (Rao et al., 1976).

Another major difference between the two schools lies in their estimates for covariance. The Hawaiian school, using Jencks et al.'s (1972) American data and a path model, have obtained an estimate on the order of 10%. The Birmingham school, using Burt's (1966) data, have found no evidence for covariance. This is to be expected, since Burt's data derive from adjusted assessments. But even in the case of Jencks et al.'s data, they have obtained the same zero result (Jinks & Eaves, 1974). This failure to detect covariance in Jencks et al.'s data throws considerable doubt on the power they claim for their method of weighted least squares (see below).

The Hawaiian school (Rao et al., 1976) have obtained the remarkable result that IQ heritability (i.e., the proportion of the total IQ variance to be attributed to hereditary factors) is very much greater for children than for adults: 67% compared with 21%. As I have shown in a recent publication (Gourlay, 1978), this result has practical (or empirical) implications that are very difficult to accept. For example, it follows that whereas the correlation between siblings (as children) is .53, the correlation between siblings (as adults) is .74. The difficulty is almost certainly due to the omission of dominance from the genetic model.

A feature of both schools is their use of high-powered statistical techniques—maximum likelihood and weighted least squares—in which all the data under consideration are combined in the one analysis with due weight being given to each item. Both these methods provide not only standard errors for the parameter estimates obtained but also tests of goodness of fit of the models employed.

On the face of it, the statistical methods used by the schools compare very favorably with the piecemeal type of analysis of Jencks, Burt, and others. On the other hand, the piecemeal approach permits the application of corrections for various error factors that affect the raw data (e.g., the selective placement factor in the case of foster-child studies). By not allowing for such factors, the parameter estimates of the schools are given a precision that can be quite spurious. Thus, applying weighted least squares to Jencks et al.'s data, Jinks and Eaves (1974) obtained an estimate of $.29 \pm .02$ for the environmental variance between families. The figure is almost certainly inflated by selective placement, for which Jinks and Eaves made no allowance. It is also significant that the application of their method to Jencks et al.'s (1972) data gave no evidence of covariance; apparently the method is just not sensitive enough to reveal the covariance that is undoubtedly there.

The present study does not use the methods of maximum likelihood or weighted least squares, but follows the general approach of Jencks. As justification, it can be argued (a) that by correcting or adjusting data for all relevant factors before the final analysis, one is more likely to obtain a solution that is consistent with all the known facts and (b) that this is preferable to the use of high-powered methods, which yield standard errors and tests of goodness of fit but produce parameter estimates that are obviously unacceptable empirically.

Although following the general approach of Jencks, the present study contains a number of important modifications, in one or two cases amounting to actual corrections:

1. A more critical examination is made of the data that derive from the four classical foster-child studies: Burks (1928), Freeman, Holzinger, & Mitchell (1928), Leahy (1935), and Skodak and Skeels (1949). This examination has the effect of largely removing the discrepancy that Jencks et al. found between the results obtained from the analysis of foster-child-study data and kinship correlations.

2. A new principle is introduced that has not so far appeared in heritability analysis, namely, that the genotypic value (G) is a function of age as well as ability. Its introduction removes two major difficulties that Jencks et al. encountered: (a) their failure to reconcile an item of the Skodak and Skeels data with their basic analysis (in the end, they dismissed the Skodak and Skeels study as "deviant" [Jencks et al., 1972, pp. 281–283]) and (b) the problem of explaining the large difference that exists between the correlations for siblings and fraternal twins (about 11%–12% of the total IQ variance). The general effect of introducing the new principle into heritability analysis is to increase the estimate of the hereditary component and to decrease the estimate of the environmental component.

3. In applying their basic path model (Jencks et al., 1972, pp. 279–281) Jencks et al. appeared to assume that the path coefficients from the child's G and E (environmental value) to his IQ were the same for the foster child as for the child living with his parents. This is an oversight and is corrected in the present analysis.

4. Jencks et al. have been criticized for not making their application of Fisher's (1918) genetic theory more explicit. Thus Jinks and Eaves (1974) felt that a weakness of their approach was their failure to deal systematically with dominance. Also, in one of their own notes (Jencks et al., 1972, p. 317) there is a cryptic reference to a comment by Crow that charges them with ignoring the effects of dominance. The present study attempts to set out more clearly Jencks et al.'s use of genetic theory. In particular, it corrects their formula for the genotypic correlation between fraternal twins, in which they confuse the genotypic correlation between spouses with the correlation between their additive deviations.

The outcome of the new analysis is a solution that appears to be consistent with all the data relevant to IQ heritability analysis. It supports Jencks in his estimate for covariance, but is closer to Burt and Jensen in its estimate of the relative importance of hereditary and environmental differences.

Theoretical Basis of Analysis

The Basic Model

IQ heritability analysis invariably starts with a simple additive model:

$$\textit{measured intelligence}\ (\text{IQ}) = G + E, \quad (1)$$

where in genetic terminology, IQ is the phenotypic, G the genotypic, and E the environmental value. The corresponding variance equation is

$$\text{var (IQ)} = \text{var}\ (G) + \text{var}\ (E) + 2\ \text{cov}\ (GE), \quad (2)$$

where cov (GE) is the covariance between G and E.

If one standardizes all three variables (i.e., with $M = 0$ and $SD = 1$), then, applying Jencks et al.'s notation, one can write

$$Q = hG + eE, \quad (3)$$

where Q represents IQ (standardized). The corresponding variance equation is now

$$1 = h^2 + e^2 + 2hes, \quad (4)$$

where h^2 and e^2 represent the fractions of the total IQ variance due to hereditary and environmental differences, respectively, and $2hes$ represents the fraction due to covariance, s being the correlation between G and E.

Genetic–environmental interaction. Some critics (e.g., Layzer, 1974) would insist that Equations 1 and 3 should also contain a term that represents genetic–environmental interaction (in the statistical sense). This would also mean additional terms in Equations 2 and 4. However, the most likely form of the interaction is a product term in G and E, and it can be shown that for such a term the variance is negligible. It follows that for the purpose of heritability analysis, it is fairly safe to omit genetic–environmental interaction from the basic model.

The age factor. Heritability analysis in the case of plants and animals (excluding humans) usually involves variables that characterize the mature organism, for example, size and quality of fruit or crop, milk and beef yields, and so on. The factor of age does not normally enter into the analysis. Consequently, it is generally assumed that (a) for a given population, h and e are fixed (i.e., heritability is a constant for the population) and (b) for any member of the population, G is fixed.

The same assumptions are to be found in the field of IQ heritability analysis (there is one exception). Yet, it is obvious that IQ herita-

bility analysis is different from plant and animal analysis in that since much of the data concerns children with ages ranging from 4 to 17 years, one is no longer dealing with a homogeneous population of mature individuals. Consequently, there is a distinct possibility that G varies with age and that even when heritability analysis is confined to children of the same age (x), the values of h and e also vary with x. It appears, therefore, that to allow for the age factor, Equation 3 should be written in the form

$$Q_x = h_x G_x + e_x E_x, \quad (5)$$

where x indicates that h, e, and G as well as Q and E can vary with age.

Following Wright (1931), the Hawaiian school of biometrical genetics have gone some way toward recognizing the importance of an age factor. They allow for the possibility that h and e can vary with age, but still make the standard assumption that G for the individual is fixed. As a result of their analysis, they give two values for h^2 and e^2: the values for a child population—a sort of average over all the ages involved—and the values for an adult population (Rao et al., 1976). The values are $h^2 = .670$ and $e^2 = [.094$ (common environment) $+ .135$ (residual)$]$ for the child population and $h^2 = .211$ and $e^2 = [.506$ (common environment) $+ .151$ (residual)$]$ for the adult, where *common environment* means common family environment. The estimates for the covariance ($2hes$) are .101 and .132, respectively.

As indicated earlier, these results have some rather strange empirical implications. In particular, it follows from the Hawaiian estimates that the correlation between the IQs of the adopted child and the natural mother is .26; but when the adopted child becomes an adult, the correlation falls to .15. This deduction is quite at variance with the Skodak and Skeels (1949) data, in which the correlation between adopted child and natural mother increases from about .28 to about .40 as the (average) age for adopted child moves from 4 years 3 months to 13 years 6 months.

The most likely explanation of the oddness of the Hawaiian results is the omission of dominance from their genetic model. But there is another important aspect to consider. Ignoring selective placement, it follows from Equation 5 that the IQ correlation between adopted child (AC) and natural mother (NM) is given approximately by

$$r(Q_{\mathrm{AC}x}, Q_{\mathrm{NM}}) = h_x r(G_{\mathrm{AC}x}, Q_{\mathrm{NM}}).$$

Consequently, if G_{AC} does not vary with x, $r(G_{\mathrm{AC}}, Q_{\mathrm{NM}})$ will be a constant, and the correlation between $Q_{\mathrm{AC}x}$ and Q_{NM} will vary directly with h_x. Thus if h_x decreases with x (the Hawaiian case), the correlation $r(Q_{\mathrm{AC}x}, Q_{\mathrm{NM}})$ will also decrease with x. On the other hand, if the correlation between the two IQs increases with x, as is suggested by the Skodak and Skeels data and as one might expect on a priori grounds, then either h_x must increase with x or $r(G_{\mathrm{AC}x}, Q_{\mathrm{NM}})$ must increase with x (or both). The first alternative is not likely. So it appears that the second alternative must hold, that is, the correlation between $G_{\mathrm{AC}x}$ and Q_{NM} will increase with x. It follows that G_{AC} (or simply G) varies with age x. This principle, that G varies with age, is an important feature of the analysis provided in this study. It is discussed more fully in the next section.

There remains the question of whether h and e also vary with age. Most likely there is some variation of h and e with age, and it is very probable that it takes the form of a decreasing h and an increasing e. However, for the purposes of the present study, it is assumed that no serious error will be incurred if, for ages 5 years and onwards, one takes h and e as constant and therefore also the covariance ($2hes$). The basic model for the study is therefore

$$Q_x = hG_x + eE_x, \quad (6)$$

where Q_x, G_x, and E_x vary with age x.

The Genotypic Value (G) *as a Function of Age and Ability*

Probably the main reason why past investigators have universally accepted a fixed G is that the genotype is fixed at conception. However, it must also be remembered that genetic development is a program in time that unfolds as the organism interacts with its environment. Different genetic factors operate at different points in time; moreover, the time schedule varies from individual to individual. It follows therefore that G must vary with age.

In the case of an intelligence test, such as the Stanford-Binet, this should be easily accepted, since it is well-known that the factor

content at any one age is different from that at another. But even in the case of a unidimensional variate such as height, the Gs for any two ages will not be the same (except, of course, at maturity). Obviously, in the case of different abilities, for example, the ability to read and the ability to do an intelligence test, it follows a fortiori that the Gs for one ability will not be the same as those for the other, even at the same point in time.

How does G for an IQ test such as the Stanford-Binet vary with age? Actually the pattern of variation is very similar to that for IQ itself. If the correlation between IQ at age 16 or 17 and IQ at an earlier age x is plotted against x, the curve obtained is a rising curve that levels out to the value of one at $x = 16$ or 17 (cf. Jensen, 1969, p. 18). In the case of G, the corresponding curve is similar in form and lies below the IQ curve, except at age 16 or 17 where the two curves come together. For the moment I simply demonstrate this result; later I derive it from the Skodak and Skeels data. (See Figure 1 on p. 612.) The demonstration depends on taking the results for a typical heritability analysis, say, those of Jencks et al. (1972), and assuming that h, e, and s are constant with age (see above).

According to Jencks, an acceptable analysis of the total IQ variance would be the following: heredity, 46.5%; environment, 35% (20% between families and 15% within a family); and covariance, 18.5%. Equationwise, Jencks et al.'s solution can be expressed

$$Q = .682G + .447EF + .387ER, \qquad (7)$$

where EF and ER are the between-families and within-family environmental measures and all four variates Q, G, EF, and ER have been standardized ($M = 0; SD = 1$).

Consider now a particular value of x, say, $x = 5$. According to Jensen (1969, p. 16), the correlation between IQs at ages 5 and 16 (or 17) is about .70, when correction is made for attenuation. It follows from Equation 7 that

$$.70 = .465r(G5, G16) + .20 + .15r(ER5, ER16) + .185,$$

where $G5$ represents the value of G at age 5, and so on. The correlation $r(ER5, ER16)$ cannot be zero. One can easily imagine that at least a quarter of the within-family environmental variance is accounted for by age 5. Let me therefore take .50 as the value for this correlation, recognizing that it could well be an underestimate. Substituting in Equation 6 one finds that $r(G5, G16) = .24/.465 = .516$. Obviously, the value of G at age 5 is considerably different from the value of G at age 16. Furthermore, it follows that the curve for $r(Gx, G16)$ lies below the curve $r(Qx, Q16)$.

The above has been worked out on the basis of Jencks et al.'s solution that did not apply the principle that G varies with age. Naturally, it would be just as easy to carry out the demonstration using a solution that incorporated the principle.

Implications of the variability of G *with age.* The recognition of the principle of the variability of G with age has two immediate consequences. First, any definition of G must specify not only the population and the IQ test for which G is being defined but also the age group. Following Falconer (1967, p. 113), one might define the genotypic value for a given IQ test at age x as follows:

If one would replicate the genotype in a number of individuals and measure them for IQ at age x, after they lived in environmental conditions normal for the population, their mean environmental deviation would be zero, and their mean phenotypic value (i.e., IQ) would consequently be equal to the IQ genotypic value of that particular genotype at age x.

Second, the basic model must show that G as well as E and Q varies with age. This, of course, has already been done (see Equation 6). There are several other important consequences:

1. The variation in the correlation between IQ at 16 years of age and IQ at earlier ages has often been quoted as evidence of the inconstancy of IQ, that is, that IQ varies considerably as a result of environmental change. The introduction of the principle that the genotypic value varies with age provides a different explanation for the inconstancy, namely, that most of the variation is of a genetic character. Even on the basis of the simple demonstration presented earlier, it appears that environmental change accounts for no more than a quarter of the change in the IQ correlation with age.

There is an obvious parallel with Piaget's theory of stages in cognitive development. Piaget's theory, although interactionist, is essentially genetic in character—certainly implicitly so—and it is possible to argue that the principle of the variability of G with age is a translation of Piaget into statistical terms.

2. The correlation between the genotypic values of siblings is not independent of the ages of the siblings—as is generally assumed—but varies with the age interval between them. The greater the age interval, the smaller the correlation. In fact, if one considers children of age 16 and their siblings at earlier ages x, the correlation between the Gs of the sibling pairs (one at age 16 and one at age x) varies with x in the same manner as $r(Gx, G16)$, except that the maximum value (at $x = 16$) is on the order of .50.

It follows that the correlation between the IQs of ordinary siblings is depressed vis-à-vis the correlation for fraternal twins—not just because of greater environmental differences but also because of the greater differences in their Gs. This, of course, clears up the problem, which obviously worried Jencks, of how to explain the large difference between the correlations for siblings (different ages) and those for fraternal twins (same age): .59 versus .70 (Jencks et al., 1972, pp. 289; 290).

3. In the same way, the correlations between the Gs for child and parent vary with the age of the child. Skodak and Skeel's (1949) study is unique in that it provides confirmatory empirical evidence. The result also explains Burt's (1966) finding that the correlation between parent (adult) and child is .50, whereas the correlation for parent (as child) and child is .56 (cf. Jensen, 1969, p. 49; Kamin, 1974, pp. 94; 95).

4. It should now be apparent that the principle of G variability with age has important implications for heritability analysis. Previous analyses have been wrong in that they have ignored differences in age between parent and child and between siblings. Obviously, analyses must be carried out on data for which the Gs are at the same age level, and where the data are not in this form to begin with, they must be adjusted so that the Gs are comparable. Oddly enough, Burt, who has been subjected to so much criticism of late, largely avoided the problem of G variability by concentrating on twin data in which age differences did not operate.

The Genetic Model

It follows from the definition of G, as also from the basic model (Equation 6), that G includes all the underlying genetic factors. In the literature, there is some confusion on this point in that the term *genotypic value* is sometimes applied only to additive genetic effects (genetic interaction effects such as dominance are treated as phenotypic). However, for the purposes of this study, it must be made clear that G embraces not only additive effects but any other genetic effects one chooses to consider.

An examination of IQ heritability studies shows that only three main genetic effects are considered: (a) additive effects if mating were random, (b) additive effects due to assortative mating (the concept that mating is not random and that the additive effects of spouses are correlated), and (c) dominance (the concept that the genes at any one locus can interact and produce a nonadditive effect). Other genetic factors are possible, for example, epistasis (the concept of interaction between genes at different loci), but it is generally assumed that these effects are not important for IQ heritability analysis and can be ignored.

In restricting genetic factors to these three main effects, IQ heritability analysis follows the classical genetic theory of Fisher as laid down in his 1918 article. The present study, like other studies, does not attempt to advance on this theoretical basis.

Expressing the genetic model in equation form, one can write $G = A + D$, where A = additive effects (including assortative mating) and D = dominance effects. The corresponding variance equation is

$$V_G = V_A + V_D. \tag{8}$$

There is no covariance term, A and D being uncorrelated.

The additive variance V_A is often termed the genic variance and can be split into two subcomponents: (a) the variance due to additive effects if mating were random and (b) the additional additive variance due to assortative

mating. Burt (1975, p. 127) called these two components the additive variance (V_A) and the variance due to assortative mating (V_{AM}). But to avoid confusion, I call them both additive variance and denote them by $V_{A(R)}$ and $V_{A(AM)}$; that is, Equation 8 can be written

$$V_G = V_{A(R)} + V_{A(AM)} + V_D.$$

I now standardize G, A, and D (with $M = 0$ and $SD = 1$) and write

$$G = aA + dD, \tag{9}$$

where

$$1 = a^2 + d^2, \tag{10}$$

$$a^2 = V_A/(V_A + V_D),$$

and

$$d^2 = V_D/(V_A + V_D);$$

that is, a^2 and d^2 are the proportions of the genotypic variance to be attributed to additive effects and dominance, respectively. Also, it should be noted that the term a^2 is equivalent to c_2 in Fisher's (1918) analysis.

I now consider the relationship between the genetic measures for parents and offspring. In the discussion that follows, it is understood that the Gs, As, and Ds have been defined for the same age (or level) of development; that is, either children's values have to be defined for the adult level or parents' values have to be defined for the same age as the children. I assume the former. The Gs, As, and Ds for father, mother, and offspring are distinguished by subscripts F, M, and C, respectively.

Since the child gets half of his genes from each parent, it follows that

$$A_C = .50(A_F + A_M) + \textit{random term} \text{ (within family)}. \tag{11}$$

A similar equation can be written that expresses G_C in terms of G_F and G_M, namely,

$$G_C = g(G_F + G_M) + \textit{random term} \text{ (within family)}, \tag{12}$$

where the same symbol (g) is used as in Jencks et al. (1972).

The coefficient g will not be .50, since G includes dominance as well as additive effects. It is important that one obtain an expression for its magnitude.

As a first step, it might be noted that the correlation between G_C and the G of either parent (G_P) is

$$r(G_C, G_P) = g[1 + r(G_F, G_M)],$$

which can be written

$$r(G_C, G_P) = g(1 + p), \tag{13}$$

where $r(G_F, G_M) = p$ (Jencks et al.'s notation) $= \mu$ (Fisher's notation). (It might be noted that Fisher used the same symbol μ to denote both the correlation between the genotypic values and the correlation between the phenotypic values.)

The correlation $r(G_F, G_M)$ implies assortative mating. It is assumed as in Jencks et al. that G_F and G_M are correlated through the IQs of the parents. It follows that

$$p = r(G_F, G_M) = r(G_F, Q_F)r(Q_F, Q_M)r(Q_M, G_M).$$

But by Equation 3,

$$r(G_F, Q_F) = h + es = r(Q_M, G_M).$$

Hence

$$p = (h + es)^2 r(Q_F, Q_M), \tag{14}$$

which is Jencks et al.'s (1972, p. 273) result.

Similarly, following Fisher's genetic model, as did Jencks et al., A_F and A_M are correlated through G_F and G_M, where

$$r(A_F, A_M) = a^2 r(G_F, G_M) \tag{15}$$

(see Equation 9).

Denoting $r(A_F, A_M)$ by A as in Fisher (Jencks et al. made the mistake of omitting A from their analysis), one has $A = a^2 p = c_2\mu$ (Fisher's notation). (This equation is not to be confused with the other well-known equation of Fisher, $A = c_1c_2\mu$. As noted earlier, Fisher used μ in two senses. When μ denotes the correlation between the *genotypic* values of parents, $A = c_2\mu$. But when μ denotes the correlation between their *phenotypic* values, $A = c_1c_2\mu$. It would have been better if Fisher had used two symbols, say, μ_g and μ_p.)

Corresponding to Equation 15, one also has $r(D_F, D_M) = d^2p$ and $r(A_F, D_M) = adp = r(A_M, D_F)$. By means of these equations, one can derive another expression for $r(G_C, G_P)$

Table 1
Summary of Relationships Between Genetic Components in Fisher's (1918) and Jencks et al.'s (1972) Terminology

Component	Fisher	Jencks et al.
$r(G_F, G_M)$	μ	$p = (h + es)^2 r(Q_F, Q_M)$
$a^2 = V_A/(V_A + V_D)$	c_2	$2g$
$r(A_F, A_M)$	$A = c_2\mu$	$2gp$
$r(G_C, G_P)$	$.5c_2(1 + \mu)$	$g(1 + p)$
$r(G_1, G_2)$	$.25(1 + c_2 + 2c_2A)$	$.25 + .5g + 2g^2p$
$V_{A(R)}/(V_A + V_D)$	$c_2(1 - A)$	$2g(1 - 2gp)$
$V_{A(AM)}/(V_A + V_D)$	c_2A	$4g^2p$
$d^2 = V_D/(V_A + V_D)$	$1 - c_2$	$1 - 2g$

as follows:

$$r(G_C, G_P) = E[(aA_C + dD_C)(aA_P + dD_P)]$$
$$= E\{(aA_P + dD_P)[.50a(A_F + A_M) + dD_C + \textit{random term}]\}$$

(by Equation 11; where E = expected value). Assuming that the correlation between D_C and D_P is negligible, this becomes

$$r(G_C, G_P) = .50a^2(1 + A) + .50ad(adp),$$

which reduces to

$$r(G_C, G_P) = .50a^2(1 + p). \tag{16}$$

Comparing Equations 13 and 16, it is seen that $g = .50a^2 = .50c_2$ (Fisher's notation); that is, c_2(Fisher) $= 2g$(Jencks) $= a^2$.

Since it is required later, I also derive the correlation between the genotypic values for fraternal twins (or siblings at the same age). Thus, one can write

$$r(G_1, G_2) = E[(aA_1 + dD_1)(aA_2 + dD_2)]$$
$$= E\{[.50a(A_F + A_M) + dD_1 + \textit{random term}] \times [.50a(A_F + A_M) + dD_2 + \textit{random term}]\}.$$

It must now be noted that whereas the Ds for offspring are uncorrelated with the As and Ds for parents, the Ds for siblings are correlated. I assume the standard figure for the correlation, namely, .25 (cf. Falconer, 1967, p. 157). It follows that

$$r(G_1, G_2) = .25a^2(2 + 2A) + .25d^2,$$

which, using Equation 10, reduces to

$$r(G_1, G_2) = .25 + .25a^2 + .50a^2A$$
$$= .25(1 + c_2 + 2c_2A) \text{ (Fisher)}$$

or

$$r(G_1, G_2) = .25 + .50g + 2g^2p \text{ (Jencks)}. \tag{17}$$

This equation corrects Jencks et al.'s mistake (1972, p. 303): They seem to have assumed that p, the correlation between parental Gs, is the same as the correlation between their additive deviations.

Table 1 summarizes a number of the above results and includes expressions for the components of the genetic variance. In each case, both Fisher's and Jencks's terminology are presented.

The Analysis

The general approach is that of Jencks et al. (1972). In other words, a solution is sought mainly through data on the correlations between parents and children, both natural and foster. The only other item of data of equal importance is the correlation for fraternal twins (of the same sex). The twins correlation has the advantage over the correlation for ordinary siblings in that because twins are of the same age, their Gs are comparable. This permits the immediate application of Fisher's (1918) genetic theory (see, in particular, Equation 17).

As in Jencks, all correlations are corrected for attenuation. Error terms do not therefore appear in the variance analysis.

Notation

The symbols NC and AC are used to denote natural (own) and adopted child; NP, NF, and NM and AP, AF, and AM are used to denote natural and adopting parent, father, and mother, respectively. The symbol Q is used for IQ (standardized); but in the case of correlations involving IQs, it is normally omitted from the notation, except where there could be confusion. Thus, $r(\mathrm{F}, \mathrm{M})$ denotes the correlation between the IQs of parents (corrected for attenuation) and $r(\mathrm{AC}x, \mathrm{NM})$ denotes the correlation between the IQs of adopted child at age x and natural mother. On the other hand, a correlation such as $r(G_{\mathrm{NC}x}, Q_{\mathrm{NM}})$ retains the Q in the notation.

Three expressions that occur frequently in the analysis are represented by special symbols. These are $\alpha = (h^2 + e^2)^{\frac{1}{2}}$, $Y_x = r(\mathrm{NC}x, \mathrm{NP})$, and $Z = r(\mathrm{AC}, \mathrm{AM}; \mathrm{NSP})$, where NSP indicates the correlation between AC and AM with no selective placement.

Basic Data

A large part of the data is taken from Jencks et al. (1972), who provide an excellent summary of American data related to IQ heritability analysis. The first two important items are (a) the correlation between the IQs of father and mother (the empirical measure of assortative mating), $r(\mathrm{F}, \mathrm{M}) = .57$, and (b) the correlation between the IQs of parent and own child living with parent.

Jencks et al.'s study gives an estimate of .55 for the latter correlation, but the statistic has to be qualified. One must remember that in accordance with the principle of the variability of G with age, $r(\mathrm{NC}, \mathrm{NP})$ will vary with the age level of the children from whose IQs the correlation was derived—The younger the children, the lower the correlation. It is assumed that the figure of .55 applies to children whose ages are about average for foster-child studies. I take this average as 9.3 years, the figure for the Leahy (1935) study. I therefore write

$$Y_{9.3} = r(\mathrm{NC}9.3, \mathrm{NP}) = .55. \qquad (18)$$

Also important is the correlation between the IQs of fraternal twins. It is assumed that the correlation is independent of the age level of the twins. Also, like Jencks, I take the figure provided by the Newman, Freeman, and Holzinger (1937) study; that is, I write

$$r(1, 2) = .692 = r_{\mathrm{IQDZT}} \quad \text{(Jencks et al.'s notation)}. \qquad (19)$$

This statistic is considerably larger than the .59 (corrected for attenuation) reported by Burt (1966). However, as Kamin (1974) pointed out, there are several large-scale studies that support the Newman et al. figure. Also, as has already been argued, the principle of the variability of G with age implies a figure rather higher than the .57 generally accepted for siblings. (One must remember also that the factor of greater environmental differences for siblings vis-à-vis twins further increases the difference between the two correlations.) Finally, Jencks et al. provide data from the four foster-child studies: Burks (1928), Freeman (1928), Leahy (1935), and Skodak and Skeels (1949).

Together the studies provide an estimate of $Z = r(\mathrm{AC}, \mathrm{AM}; \mathrm{NSP})$. The Skodak and Skeels study is of particular importance in that it furnishes data that are used to derive the variation of $r(G_{\mathrm{NC}x}, Q_{\mathrm{NM}})$ with age x and also of $r(Gx, G16)$ with x.

Basic Equations

The equations required for the analysis are set out below. Their derivation, together with underlying assumptions, is briefly indicated in the Appendix.

1. For children living with their natural parents,

$$Q_{\mathrm{NC}x} = hG_{\mathrm{NC}x} + eE_{\mathrm{NC}x}. \qquad (20)$$

This, of course, is the same as Equation 6.

2. For foster children with no selective placement,

$$Q_{\mathrm{AC}x} = (1/\alpha)(hG_{\mathrm{AC}x} + eE_{\mathrm{AC}x}), \qquad (21)$$

where $\alpha = (h^2 + e^2)^{\frac{1}{2}}$. Obviously, it is assumed that the genetic and environmental variances are the same for foster children as for own children or, at least, that the data can be adjusted in accordance with this assumption. The covariance for foster children is of course zero if there is no selective placement.

In the case of a moderate degree of selective placement (as for the Burks, Leahy, and Skodak and Skeels studies—Freeman is the exception), it can be shown that little error is involved in assuming that Equation 21 still holds (see Appendix).

3. For foster child and foster parent (no selective placement),

$$Z = r(\mathrm{AC}, \mathrm{AP}; \mathrm{NSP}) = (e/\alpha)r(E_{\mathrm{NC}}, Q_{\mathrm{NP}}). \quad (22)$$

4. For foster child and foster mother (SP refers to selective placements),

$$r(\mathrm{AC}x, \mathrm{AM}; \mathrm{SP}) = Z + (h/\alpha)r(G_{\mathrm{NC}x}, Q_{\mathrm{NM}})r(\mathrm{NM}, \mathrm{AM}); \quad (23)$$

that is, the correction for obtaining Z from

$$r(\mathrm{AC}x, \mathrm{AM}; \mathrm{SP}) = -(h/\alpha)r(G_{\mathrm{NC}x}, Q_{\mathrm{NM}})r(\mathrm{NM}, \mathrm{AM}). \quad (24)$$

5. For parent and own child,

$$Y_x = r(\mathrm{NC}x, \mathrm{NP}) = hr(G_{\mathrm{NC}x}, Q_{\mathrm{NP}}) + \alpha Z. \quad (25)$$

Assuming that for $x = 16$, the Gs for children and parents are comparable, one can write

$$hr(G_{\mathrm{NC}16}, Q_{\mathrm{NP}}) = gh(h + es)[1 + r(\mathrm{F}, \mathrm{M})], \quad (26)$$

where g is defined as earlier (see Equation 12).

6. For covariance,

$$2hes = \frac{4\alpha Z}{1 + r(\mathrm{F}, \mathrm{M})}(Y_{16} - \alpha Z). \quad (27)$$

7. For foster child and natural mother,

$$r(\mathrm{AC}x, \mathrm{NM}; \mathrm{NSP}) = r(\mathrm{AC}x, \mathrm{NM}; \mathrm{SP}) - Zr(\mathrm{NM}, \mathrm{AM}), \quad (28)$$

where the second term on the right-hand side is the correction for selective placement. Also,

$$r(\mathrm{AC}x, \mathrm{NM}; \mathrm{NSP}) = (h/\alpha)r(G_{\mathrm{NC}x}, Q_{\mathrm{NM}}). \quad (29)$$

8. For fraternal twins (of the same sex),

$$r(1, 2) = h^2 r(G_1, G_2) + 2hes + e^2 r(E_1, E_2), \quad (30)$$

where it is assumed that

$$s = r(G_1, E_1) = r(G_2, E_2) = r(G_1, E_2) = r(G_2, E_1).$$

For identical twins living together, it is generally accepted that the environmental variance within a pair of twins is .03 (3%). According to Jencks et al. (1972, p. 308), the environmental variance within a fraternal twin pair is not likely to be much more than .03. But some critics would regard this as a rather tenuous assumption. Thus, Kamin (1974, p. 99), referring to data from same-sex and opposite-sex fraternal twins, argued that the environmental variance for fraternals must be considerably higher than that for identicals. However, there is evidence that the IQ variance for boys is greater than that for girls (cf. Publications of the Scottish Council, 1949), and it can be argued that the data to which Kamin refers are more easily explained on the basis of greater genetic variance for boys than for girls. This would mean, of course, that there should be a difference in IQ heritability between boys and girls and that the result of all "mixed" analyses, like that of the present study, is only an average for the sexes.

Nevertheless, for the moment, I treat the environmental variance within a fraternal twin pair as an unknown quantity and denote it by ω; that is, $e^2 r(E_1, E_2) = e^2 - \omega$. Equation (30) then becomes

$$r(1, 2) = h^2 r(G_1, G_2) + 2hes + e^2 - \omega. \quad (31)$$

The genetic correlation $r(G_1, G_2)$ is given by Equations 14 and 17. Substituting in Equation 31, one obtains

$$r(1, 2) = h^2[.25 + .50g + 2g^2(h + es)^2 r(\mathrm{F}, \mathrm{M})] + 2hes + e^2 - \omega. \quad (32)$$

Outline of Analysis

The first step is to obtain an estimate of $Z = r(\mathrm{AC}, \mathrm{AM}; \mathrm{NSP})$. The figure adopted was the average of four estimates, one from each of the four foster-child studies. Since this involved the application of corrections for selective placement, dependent for their value on the final solution, a reiterative method had to be employed for the analysis as a whole; that is, initially approximations to these corrections were used. Then when a solution was obtained that had been derived from these values, the corrections were revised. The

procedure was repeated until no further revision was required.

For simplicity of presentation, the reiterations are omitted from the account that follows, and only the final values for the corrections appear. Since $\alpha = (h^2 + e^2)^{\frac{1}{2}}$ is involved in these corrections, the final value for α is assumed in making this simplified presentation. It follows that in completing the analysis, it is necessary to show that the values finally obtained for h^2 and e^2 are consistent with the initially assumed value for α. The remaining steps of the analysis are as follows:

1. Values are found for $hr(G_{NC16}, Q_{NP})$ in Equation 26 and for Y_{16} in Equation 27. Details of this are presented later. A value for the covariance ($2hes$) follows immediately from Equation 27; also, Equation 26 can be expressed entirely in terms of the four unknowns, g, h, e, and s.
2. Equations 26, 27, 32, and 4 can then be solved so that values for g, h, e, and s are obtained for a range of values of ω (the environmental variance within a fraternal twin pair).
3. Finally, a suitable value for ω is determined from a consideration of the likely values for e^2 (the total environmental variance) and its between-families and within-family components. Data used in making this decision are (a) the difference in the correlations for fraternal twins and ordinary siblings and (b) the results of studies of separated identical twins. With the choice of a value for ω, the other unknowns (g, h, e, and s) are fixed. One can then write down the contributions of heredity, environment, and covariance to the total IQ variance, and, using the formulae in Table 1, one can derive the $V_{A(R)}$, $V_{A(AM)}$, and V_D components of the genetic variance.

The Correlation Z = r(*AC, AM; NSP*)

The Burks (*1928*) *study.* Burks's study yielded the following statistics: r(AC, AM) = .23 and r(AC, AF) = .09, both correlations corrected for attenuation.

The correlation r(AC, AF) is abnormally low and can be shown to be the cause of the spuriously high value for the between-families environmental variance (17.6%) that Burks obtained from her multiple regression analysis. I therefore deal only with r(AC, AM). In any case, selective placement appears to operate mainly through the mothers (natural and foster); also, statistics on selective placement are usually with respect to mothers. The correction for selective placement is given by Equation 24. Assuming a value of .16 for r(NM, AM) (cf. Jencks et al., 1972, p. 277) and applying the reiterative method, one obtains a value of −.062 for the correction (the final value of α = .902); that is, it appears that Z(Burks) = .23 − .062 = .168.

A further correction for restriction in range of family environment might be necessary, but it is not likely to be large. One must simply bear in mind that the figure of .168 could be on the low side.

The Leahy (*1935*) *study.* The values obtained for r(AC, AP) were as follows: r(AC, AM) = .20 and r(AC, AF) = .15, or .214 and .161 (approximate) when corrected for attenuation. In her study, Leahy did not correct for attenuation, but did apply a correction for restriction in range. (The standard deviation of the IQs for the foster children was only 12.5.) This correction gave her values of .24 and .19, respectively, and it was these values that Jencks et al. combined with the Burks and Freeman (1928) values to get their overall mean for r(AC, AP), uncorrected for attenuation. However, a closer examination of Leahy's study shows that the small value for the standard deviation of the foster children's IQs was due mainly to a restriction in the genetic range of the foster children; a correction for this must reduce the correlations and not increase them. There was, nevertheless, some restriction in the environmental range of the foster children, as is evidenced by the fact that the standard deviation of the environmental status score was 54.3 for foster children and 59.6 for controls.

When all the necessary corrections are made, it is found that the correlation between IQ_{AC} and IQ_{AM} amounts to about .18 (because of their lengthiness, these calculations are not reproduced here); that is, Z(Leahy) = .18.

The Freeman (*1928*) *study.* This is the largest of the foster-child studies, involving 401 foster children. Correlations yielded by this study are considerably higher than those obtained in the Burks and Leahy studies. Since the average age of adoption was 4 years 2

months, selective placement is an obvious explanation, but this was resisted strongly by Freeman. The values of r(AC, AP) obtained by Freeman (uncorrected for attenuation) were r(AC, AM) = .28 and r(AC, AF) = .34. Another important statistic in Freeman's study is $r(Q_{AC}, HR) = .48$, where HR is the home rating of the foster home.

In a reanalysis of Freeman's data, to be submitted for publication, the difficulty of selective placement was avoided by a comparatively simple technique. Instead of considering the correlation between the IQs of foster children and the *HR*s of the foster homes—a procedure that cannot avoid the factor of selective placement—I estimated the IQ gains of the foster *groups* as a result of being moved from natural to foster homes. Estimates were also derived for the mean *HR*s of the natural homes—Freeman gave only the *HR*s for the foster homes—and, as a result, a measure of the mean gain in IQ per unit increase in HR was obtained. This, of course, can easily be converted to a correlation. In this way, I obtained a revised measure for $r(Q_{AC}, HR)$, which, when corrected for attenuation, amounted to only .295.

The question arises, What is the corresponding value of r(AC, AM)? It is obviously something less. As a result of further calculation, I was able to show that this correlation must be about .20; that is, Z(Freeman) = .20.

The Skodak and Skeels (1949) study. This study does not provide values for r(AC, AP). But it has the special feature of providing values for r(AC, NM) at different ages of the foster child.

The foster children were tested on four occasions, at mean ages of 2 years 2 months, 4 years 3 months, 7 years 0 months, and 13 years 6 months. In the case of 63 children (40 girls and 23 boys), the IQs were also available for the natural mothers. In all cases, the Stanford-Binet scale was used. But at the last testing (M = 13 years 6 months) the children were also given the 1937 Terman-Merrill scale. This was done in view of the inaccuracy of the Stanford-Binet standardization at the older ages.

Skodak and Skeels provided a magnificent appendix to their study, and, using the data provided there, I was able to obtain the values of r(AC, NM) at the different ages, for both boys and girls and for the two together (see Table 2). Two of the values obtained for the total group differ slightly from the correlations provided by Skodak and Skeels (in particular, the Terman-Merrill value for 13 years 6 months).

Table 2
Correlations Between IQs of Foster Child (AC) and Natural Mother (NM) for Different Ages of the Foster Child

M age (*years–months*)	r(AC, NM) Girls	Boys	Total
2–2[a]	.202	−.248	.037 (.00)[b]
4–3	.299	.233	.275 (.28)
7–0	.363	.330	.348 (.35)
13–6	.520	.066	.381 (.38)
13–6[c]	.472	.292	.415 (.44)

Note. The correlations were derived from Skodak and Skeels's (1949) data and are uncorrected for attenuation; for girls, n = 40; for boys, n = 23.
[a] Both children's and mothers' IQs were derived from the Stanford-Binet scale.
[b] Correlations in parentheses are figures given by Skodak and Skeels (1949).
[c] Children's IQs were derived from the Terman-Merrill scale and mothers' IQs from the Stanford-Binet scale.

Three things should be noted:

1. The effect of selective placement, as Jencks et al. (1972, p. 282) pointed out, is relatively unimportant. The correction is $-Zr$(NM, AM) (see Equation 28), which for r(NM, AM) = .16 and Z = .20 works out at −.032 (approximate). (It is understood that in correcting for selective placement, the same correction has to be applied to all correlations in Table 2.)

2. From an examination of Table 2, it is seen that for both girls and the total, the correlations increase steadily with chronological age. When a curve is fitted to the data, one obtains a rising curve that flattens out at the later ages. In the case of the correlations for the boys, the same trend is discerned, but the figures are very erratic. Sampling error obviously comes to mind.

3. With the number of boys and girls amounting to only 40 and 23, respectively, the degree of sampling error can be large. If one thinks in terms of a rising curve, the effect is

to raise or lower the position of the curve but not to change its general shape. Later analysis appears to indicate that sampling error is positive for the girls and distinctly negative for the boys. Furthermore, partly as a result of its greater homogeneity and smaller size, the boys' group shows greater fluctuation in its correlations. Also, despite the general homogeneity of the boys' group, the IQs for one boy and his natural mother lie well outside the range of the others, and this, together with the faulty Stanford-Binet standardization, adds considerably to the erratic variations in the correlations for the group. These irregularities also show to some extent when the boys are combined with the girls and the correlations for the total group are obtained.

In view of these considerations, it is obvious that one has a certain amount of difficulty in deciding what one should take as the value of $r(\mathrm{AC, NM})$ for the four mean ages of the Skodak and Skeels study. Despite the obvious differences in the boys' and girls' groups, I choose the values for the total group; in the case of the oldest of the four ages, 13 years 6 months, where the value is critical, I somewhat arbitrarily choose the figure .415. This estimate has at least the advantage of being almost the same as the .41 assumed by Jencks et al. (1972, p. 282).

Thus, for the four Skodak and Skeels mean ages, the values of $r(\mathrm{AC, NM})$ are .037, .275, .348, and .415 or, correcting for attenuation, .040, .299, .378, and .451.

When I now apply the correction for selective placement (−.032), the values become .008, .267, .346, and .419. In addition to these values, one requires the values for ages 8.2 and 9.3, the respective mean ages of the Burks and Leahy studies and also the value for age 16. By simple interpolation and extrapolation, these values are found to be .364, .384, and .423 (approximate); that is, at age $x = 9.3$,

$$r(\mathrm{AC9.3, NM; NSP}) = .384,$$

and therefore by Equation 29,

$$hr(G_{\mathrm{NC9.3}}, Q_{\mathrm{NM}}) = .384\alpha = .346$$

(assuming that the final value for $\alpha = .902$).

It now follows from Equation 25 that $\alpha Z = .55 - .346 = .204$, whence $Z = .204/.902 = .226$; that is, $Z(\text{Skodak and Skeels}) = .226$.

The averaged result. One now has four estimates for $Z = r(\mathrm{AC, NM; NSP})$, namely, Burks, .168; Freeman (revised), .200; Leahy, .180; and Skodak and Skeels, .226. The agreement is remarkably good. The average of the four estimates is .194, but since the figure for the Burks study is probably on the low side, I take .20 as the final estimate; that is,

$$Z(\text{final estimate}) = .20. \qquad (33)$$

This estimate is somewhat less than that of Jencks et al., which appears to be about .23 on correction for selective placement. One of the main reasons for the difference is Jencks et al.'s acceptance of the abnormally high figures produced by the original Freeman study. Another contributing factor is the mistake made by Leahy (in correcting her correlations for restrictions in range). Also, it is seen that there is now no need to reject the Skodak and Skeels study as "deviant," as did Jencks.

Derivation of Values for $\mathrm{hr}(G_{NC16}, Q_{NM})$ *and* $Y_{16} = \mathrm{r}(NC16, NM)$

As was pointed out earlier in the outline of the analysis, values are required for these two expressions in order to simplify two of the four equations required for the final solution. In deriving the values, it is necessary to correct the Skodak and Skeels $r(\mathrm{AC, NM; NSP})$ correlations for sampling error. The procedure is the reverse of that followed in estimating Z for the Skodak and Skeels study.

Assuming $\alpha = .902$ and using the overall estimate of Z as given by Equation 33,

$$\alpha Z = .902 \times .20 = .180. \qquad (34)$$

From Equations 18 and 25, it follows that

$$hr(G_{\mathrm{NC9.3}}, \mathrm{NM}) = .550 - .180 = .370.$$

Substituting in Equation 29,

$$r(\mathrm{AC9.3, NM; NSP}) = .370/902 = .410.$$

Comparing this with the value of .384 provided by the Skodak and Skeels study, it is now seen that sampling error, for boys and girls together, is small and involves a correction of only + .026; that is, the final values of $r(\mathrm{AC, NM; NSP})$ for the four ages involved in the Skodak and Skeels study are .034, .293,

.372, and .445. For ages 8.2 and 9.3, the interpolated values are .390 and .410. Last, for age 16 the extrapolated value becomes .449.

By Equation 29, it follows that

$$hr(G_{\mathrm{NC16}}, Q_{\mathrm{NM}}) = .449\alpha = .405. \quad (35)$$

Also, by Equation 26,

$$gh(h + es)[1 + r(\mathrm{F, M})] = .405$$

or, substituting for $r(\mathrm{F, M})$,

$$1.57gh(h + es) = .405. \quad (36)$$

Last, by Equations 25, 34, and 35,

$$V_{16} = r(\mathrm{NC16, NM}) = .405 + .180 = .585. \quad (37)$$

*The Covariance 2*hes

The relevant equation is 27. By Equations 34 and 37, it follows that

$$2hes = .186. \quad (38)$$

Also, $\alpha = (h^2 + e^2)^{\frac{1}{2}} = (.814)^{\frac{1}{2}} = .902$, the value used throughout the above analysis.

The estimate for the covariance (.186) is identical with that of Jencks, despite differences in the statistics. It is also much higher than the 14%–15% obtained directly from the Burks, Freeman, and Leahy studies. It should however be remembered that the environmental measures employed by these studies can only be approximate; it is possible that a more precise measure would yield a higher estimate for the covariance.

The Final Solution

As indicated earlier, four equations lead to the final solution. These are $h^2 + e^2 + 2hes = 1$ (Equation 4); $1.57gh(h + es) = .405$ (Equation 36); and $2hes = .186$ (Equation 38). The fourth equation is 32, which on substituting .692 for $r(1, 2)$ (Equation 19) and .57 for $r(\mathrm{F, M})$ becomes

$$.692 = h^2[.25 + .50g + 1.14g^2(h + es)^2] + 2hes + e^2 - \omega.$$

These four equations involve five unknowns: g, h, e, s, and ω. Since ω has a minimum value of .03 (the environmental variance within an identical twin pair) and, as Jencks et al.

Table 3
Values of h^2, e^2, *and Other Parameters Corresponding to Range of Values of* ω

	ω					
Parameter	.03	.04	.05	.06	.07	.08
$2hes$	.186	.186	.186	.186	.186	.186
g	.361	.368	.376	.383	.392	.400
h^2	.621	.607	.593	.579	.566	.552
e^2	.193	.207	.221	.234	.248	.262
s	.269	.263	.257	.253	.249	.245
$r(G_1, G_2)$	.553	.559	.566	.573	.580	.587

Note. ω = environmental variance within a fraternal twin pair.

stated, is not likely to exceed this figure by any great amount, I solve the four equations for g, h, e, and s, taking in turn values of .03, .04, . . . , .08 for ω. The results are presented in Table 3.

There remains the question of what value to choose for ω. There are two approaches to this question. The first concerns the difference between the correlations for fraternal twins and ordinary siblings: about .12 (.69 vs. .57). Jencks et al. (1972, pp. 289–209) had difficulty in trying to explain this difference. In particular, they considered the effect of the imperfections of the Stanford-Binet standardization. But probably at most these account for only .03, that is, about a quarter of the difference in correlation. In the end, Jencks et al. accepted .12 as largely representing the difference in the environmental variance within a pair for siblings vis-à-vis twins.

However, the principle of the variability of G with age is relevant here; the correlation between the genotypic values of ordinary siblings is less than that for fraternal twins—because of the age difference. A tentative analysis suggests that as much as .05 can be attributed to the G variability factor. Together with the effect of the faulty standardization, this suggests that possibly no more than .05 can be attributed to the difference in environmental variance for siblings vis-à-vis fraternal twins.

One would imagine that the difference in the environmental variance within a pair for identical and fraternal twins would be much less than that for fraternal twins and ordinary siblings—again because of the age factor—say,

Table 4
Estimates of Between-Families and Within-Family Components of Environmental Variance e^2 *for Range of Values of* ω

Variance estimates	ω .03	.04	.05	.06	.07	.08
	Present study					
Within-family component (v_R)[a]	.08	.09	.10	.11	.12	.13
Environmental variance (e^2)	.193	.207	.221	.234	.248	.262
Between-families component (v_B)	.113	.117	.121	.124	.128	.132
	Newman, Freeman, & Holzinger (1937) and Burt (1966)[d]					
e^2	.165[e]					
v_B[b]	.085	.075	.065	.055	.045	.035
% reduction in v_B due to selective placement[c]	24.5	35.9	46.3	55.6	64.9	73.5

[a] $v_R = \omega + .05$ (assuming that difference between fraternal twins and siblings for environmental variance within family is .05).
[b] Obtained by subtracting estimate of v_R (present study) from estimate of e^2 (Newman, Freeman, & Holzinger, 1937; Burt, 1966).
[c] Obtained by calculating 100 $(1 - R)$ when R = ratio of estimate of v_B (Newman, Freeman, & Holzinger, 1937; Burt, 1966) to estimate of v_B (present study).
[d] Studies used separated identical twins.
[e] Average of Newman, Freeman, and Holzinger (1937) and Burt (1966).

.01 or .02. It appears therefore that ω can be .04 or .05, but is unlikely to be more. It also follows that the environmental variance within a family is no more than .09 or .10 (i.e., 9% or 10% of the total IQ variance).

A second approach is provided by the data from studies in which identical twins are brought up separately or apart (ITA). If the twins are separated at an early age and if there is no selective placement, then the variance within a pair is an estimate of the total environmental variance (both between families and within family). The Newman et al. (1937) study gives a figure of 36.3 (corrected for error) for the variance within a pair, that is, 16.2% of the total IQ variance ($15^2 = 225$). The figure for Burt's (1966) group test IQ data is only slightly more. The weakness of ITA studies is the likelihood of a considerable degree of selective placement being involved in the assignment of the twins to their foster homes. For this reason, there is a general tendency to dismiss these studies as useless for the purpose of heritability analyses. This, however, is a mistake. An important point, which is overlooked, is that selective placement affects only between-families environmental differences; it does not affect the factors that contribute to within-family environmental differences. Consequently, the 16.5% derived from the Newman et al. and Burt studies can be regarded as the sum of two quantities: (a) the full environmental variance within a family and (b) a fraction of the environmental variance between families, depending on the degree of selective placement present. Having noted this point, one can perform the calculations presented in Table 4.

The first half of Table 4 sets out estimates of the within-family and between-families environmental variances obtained for the present study by assuming values of .03 to .08 for ω. By subtracting the within-family variance (v_R in Table 4) from the $e^2 = .165$ of the Newman et al. and Burt studies, one also obtains the estimates of the between-families variance for the ITA studies (v_B in Table 4). The differences between the figures in rows 3 and 5 can be attributed to selective placement, and in the last line of the table, the reduction

Table 5
Variation of r(*A*Cx, *NM; NSP*) *and Other Derived Functions With Chronological Age* (x)

Function	x: 2.17	4.25	7.0	8.2	9.3	13.5	16
$r(ACx, NM; NSP)$	.112	.243	.359	.390	.410	.445	.449
Corrected[a]	.034	.293	.372			.445	
$hr(G_{ACx}, Q_{NM})$[b]	.101	.219	.324	.352	.370	.402	.405
$r(Gx, G16)$[c]	.250	.541	.800	.869	.913	.991	1.000
$r(NCx, NC16; E \text{ constant})$[d]	.544	.722	.878	.920	.948	.995	1.000

Note. AC = foster child; NM = natural mother; NSP = no selective placement.
[a] The figures in this row are the four Skodak and Skeels (1949) correlations for the 63 adopted children and their natural mothers, corrected for attenuation, selective placement, and sampling error. The figures above (in the first row) were obtained by fitting a smooth curve to the four correlations (see Figure 1).
[b] Obtained by multiplying the figures in the first listed function by $\alpha = (h^2 + e^2)^{\frac{1}{2}}(=.902)$.
[c] Obtained by dividing the first listed function by .449 (see Equation 40).
[d] Obtained by multiplying the third listed function by $h^2(=.607)$ and adding .393 (see Equation 39).

in variance due to selective placement is given as a percentage. It seems very reasonable to assume that selective placement does not produce a reduction in variance greater than 50%. It follows, therefore, that ω should be in the range .03–.05.

In light of the two arguments presented above, I choose $\omega = .04$ in order to obtain the final solution. It follows from Tables 3 and 4 that the components of the IQ variance are 60.7% for heredity, 20.7% for environment (9% within a family and 11.7% between families), and 18.6% for covariance.

The solution is a compromise between Burt and Jencks. It supports Jencks et al.'s figure for covariance, but is closer to Burt (and Jensen) as far as the *relative* importance of heredity and environment is concerned (since the ratio 60.7:20.7 is approximately 75:25).

The components of the genetic variance. For $\omega = .04$, $r(G_1, G_2) = .559$ (see Table 3). It follows that the genetic variance between families is $.607 \times .599 = .339$, that is, 33.9% of the total IQ variance. The within-family component is $60.7 - 33.9 = 26.8\%$. However, in accordance with the principle of the variability of G with age, these results apply only to fraternal twins or siblings tested at the same age. For siblings of different ages, the between-families component will decrease with increase in age difference and the within-family component increase.

Turning now to Table 1, it can be shown that for $\omega = .04$, $p = (h + es)^2 r(\text{F, M}) = .460$ and $A = 2gp = 2(.368)(.460) = .330$. Also, $V_{A(\text{R})} = 2g(1 - A) = .487$ (48.7%), $V_{A(\text{AM})} = 2gA = .250$ (25%), and $V_D = 1 - 2g = .263$ (26.3%); that is, 26.3% of the genetic variance can be attributed to dominance.

A Check on the Final Solution

The method that has been described might be regarded as deriving from two hypotheses: (a) that the genotypic value G varies with age and (b) that this genetic variation with age can be measured through the variation of the correlation between the IQ of the adopted child and the IQ of the natural mother. Since the environmental component of the IQ variance is relatively small, a corollary to these hypotheses is that the variation of the correlation between IQ at a chronological age of 16 years and IQ at earlier ages can be explained mainly in terms of the variation of G with age, although changes in the individual's environment over the years must make a contribution.

Thus the solution, and therefore the rationale on which it is based, can be checked by using it to derive the correlations between the IQs of children at 16 years and their IQs at earlier ages (x) for the theoretical case in which there is no environmental change between the two ages. On the basis of the two hypotheses and the corollary just stated, I would expect the theoretical correlations to be slightly greater than the observed correlations, the difference

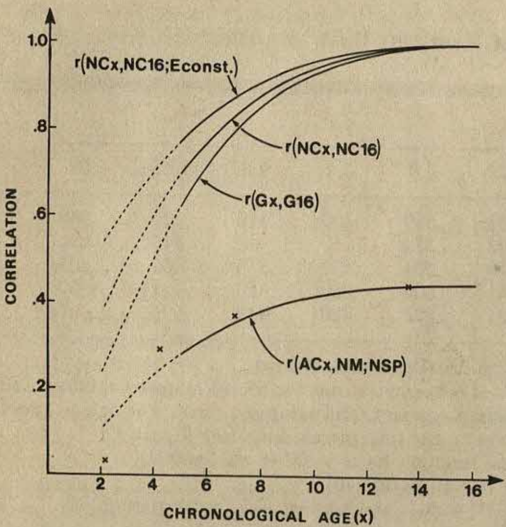

Figure 1. The variation of correlations with age (x); r(NCx, NC16; E constant) = correlation between IQ at age x and IQ at age 16 with no change in environment E; r(NCx, NC16) = correlation between IQ at age x and IQ at age 16 as obtained from empirical data; r(Gx, G16) = correlation between genotypic value at age x and genotypic value at age 16; r(ACx, NM; NSP) = correlation between IQ of adopted child at age x and IQ of natural mother with no selective placement.

(or drop) increasing with the size of the interval between the chronological ages of x and 16. Furthermore, I would expect the drop in correlation to remain well within the bounds of the total variance attributed to environmental differences (20.7%) if a reasonable amount of that variance is attributed to fairly constant environmental differences between families and also something to prenatal environmental differences. (Throughout the ensuing argument, it is understood that all correlations have been corrected for attenuation.)

For the theoretical case of no environmental change, one has for the child living with his own parents,

$$\begin{aligned} r(\mathrm{NC}x, \mathrm{NC16}; E \text{ constant}) &= E[(hG_{\mathrm{NC}x} + eE_{\mathrm{NC}x})(hG_{\mathrm{NC16}} + eE_{\mathrm{NC16}})] \\ &= h^2 r(G_{\mathrm{NC}x}, G_{\mathrm{NC16}}) + 2hes + e^2, \end{aligned}$$

making the usual assumption that covariance is constant for $x \geqslant 5$. Substituting the values for $2hes$ and e^2 provided by the final solution, one obtains

$$r(\mathrm{NC}x, \mathrm{NC16}; E \text{ constant}) = h^2 r(G_{\mathrm{NC}x}, G_{\mathrm{NC16}}) + .393. \quad (39)$$

It is necessary now to derive an expression for $r(G_{\mathrm{NC}x}, G_{\mathrm{NC16}})$ that will enable one to determine its value for any given x. I assume that

$$r(G_{\mathrm{NC}x}, Q_{\mathrm{NM}}) = r(G_{\mathrm{NC}x}, G_{\mathrm{NC16}})\, r(G_{\mathrm{NC16}}, Q_{\mathrm{NM}}),$$

whence

$$r(G_{\mathrm{NC}x}, G_{\mathrm{NC16}}) = \frac{r(G_{\mathrm{NC}x}, Q_{\mathrm{NM}})}{r(G_{\mathrm{NC16}}, Q_{\mathrm{NM}})} = \frac{r(\mathrm{AC}x, \mathrm{NM}; \mathrm{NSP})}{r(\mathrm{AC16}, \mathrm{NM}; \mathrm{NSP})} \quad (40)$$

(by Equation 29); that is, $r(G_{\mathrm{NC}x}, G_{\mathrm{NC16}}) = r(\mathrm{AC}x, \mathrm{NM}; \mathrm{NSP})/.449$, substituting the value for r(AC16, NM; NSP) obtained earlier.

By means of Equations 39 and 40, one can carry out the calculations summarized in Table 5. (The second function has been added to Table 5 to provide the values necessary for the calculation of selective placement corrections involved in the Burks and Leahy studies.)

Figure 1 gives a diagrammatic representation of the results. Also included in the diagram is the curve representing the variation of r(NCx, NC16) with x, as shown by empirical data (cf. Jensen, 1969, p. 18).

It is seen that the theoretical curve r(NCx, NC16; E constant) lies above the empirical curve r(NCx, NC16), the difference between the two correlations increasing as x decreases. However, the differences between the two correlations are quite small for $x \geqslant 5$. Thus at age $x = 5$, it amounts only to about .07.

It follows therefore that the correlation between IQ at earlier ages and IQ at age 16 can be explained mainly in terms of the variation of G with age and owes comparatively little to environmental changes with age. In other words, the analysis presented in this section provides a convincing check on the final solution and lends further support to the hypotheses and methods on which it was based.

Derivation of Basic Equations Used in the Analysis

1. For own children,

$$Q_{NCx} = hG_{NCx} + eE_{NCx} \quad \text{(Equation 20)},$$

where $h^2 + e^2 + 2hes = 1$ and $s = r_{GE}$, like h and e, is assumed to be constant for $x \geqslant 5$ years.

2. For foster children (no selective placement),

$$Q_{ACx} = (1/\alpha)(hG_{ACx} + eE_{ACx}) \quad \text{(Equation 21)},$$

where $\alpha = (h^2 + e^2)^{\frac{1}{2}}$. With no selective placement, there is no covariance. It is also assumed that the genetic and the environmental variances for foster children are the same as for own children.

In the case of selective placement, let

$$Q_{AC} = h'G_{ACx} + e'E_{ACx},$$

where $1 = h'^2 + e'^2 + e'^2 + 2h'e'r_{GE(\text{SP})}$.

Applying the same assumption as for no selective placement, it follows that

$$\frac{h'}{h} = \frac{e'}{e} = \frac{(h'^2 + e'^2)^{\frac{1}{2}}}{(h^2 + e^2)^{\frac{1}{2}}} = \frac{(1 - \text{cov}_{\text{AC}})^{\frac{1}{2}}}{\alpha},$$

where $\text{cov}_{\text{AC}} = 2h'e'r_{GE(\text{SP})}$.

In the case of the Burks, Leahy, and Skodak and Skeels studies, in which only a moderate degree of selective placement is involved, it can be shown that cov_{AC} lies in the range 0–.03. It follows that

$$h' \doteqdot h/\alpha \quad \text{and} \quad e' \doteqdot e/\alpha.$$

3. For foster child and foster parent with no selective placement (Equation 22),

$$Z = r(\text{AC, AP; NSP})$$
$$= E[(h'G_{ACx} + e'E_{ACx})Q_{AP}]$$
$$= E(e'E_{ACx}Q_{AP}),$$

since with no selective placement, there can be no correlation between Q_{AP} and G_{AC}; that is,

$$Z = (e/\alpha)r(E_{ACx}, Q_{AP}) = (e/\alpha)r(E_{NCx}, Q_{NP}),$$

assuming that parents treat foster children like their own children.

With the further assumption that the correlation of E_{NCx} with Q_{NP} is constant or approximately constant with age, it follows that

$$Z = (e/\alpha)r(E_{NC}, Q_{NP}).$$

4. For foster child and foster mother with selective placement (Equation 23),

$$r(\text{AC}x, \text{AM; SP})$$
$$= E[(h'G_{ACx} + e'E_{ACx})Q_{AM}]$$
$$= Z + (h/\alpha)r(G_{ACx}, Q_{AM}).$$

Assuming that selective placement takes place mainly through matching of mothers (natural and foster),

$$r(G_{ACx}, Q_{AM}) = r(G_{ACx}, Q_{NM})r(Q_{NM}, Q_{AM})$$
$$= r(G_{NCx}, Q_{NM})r(\text{NM, AM});$$

that is,

$$r(\text{AC}x, \text{AM; SP})$$
$$= Z + (h/\alpha)r(G_{NCx}, Q_{NM})r(\text{NM, AM}).$$

5. For parent and own child (Equations 25 and 26),

$$Y_x = r(\text{NC}_x, \text{NP})$$
$$= E[(hG_{NCx} + eE_{NCx})Q_{NP}]$$
$$= hr(G_{NCx}, Q_{NP}) + \alpha Z$$

(by Equation 22).

Assuming that at age $x = 16$, the G's of parents and children are comparable:

$$G_{NC16} = g(G_{NF} + G_{NM}) + \textit{random term};$$

that is,

$$r(G_{NC16}, Q_{NP}) = E[g(G_{NF} + G_{NM})Q_{NP}].$$

Making the same assumption as Jencks et al. (1972) and Fisher (1918), that assortative mating takes place through the phenotypic values (i.e., IQs),

$$E(G_{NF}Q_{NM})$$
$$= r(G_{NF}, Q_{NM})$$
$$= r(G_{NF}, Q_{NF})r(Q_{NF}, Q_{NM})$$
$$= (h + es)r(\text{F, M}) = E(G_{NM}, Q_{NF}),$$

whence

$$hr(G_{NC16}, Q_{NP}) = gh(h + es)[1 + r(\text{F, M})].$$

6. The derivation for covariance $2hes$ (Equation 27) is as follows: Implicit in Jencks et al.'s (1972, p. 268) path model is the assumption that the G of the child is correlated with the E entirely through the IQs of the parents. The same assumption is made here, except that in accordance with the principle of the variability of G with age, it is necessary that the G's of

parent and child be comparable, that is, belong to the same age level. It is assumed that this is so when the age of child (x) is 16. I therefore derive the covariance at age 16 in accordance with Jencks et al.'s assumption and then make the standard assumption that the value of the covariance at $x = 16$ is the same for all other ages at which $x \geqslant 5$.

$$G_{\mathrm{NC16}} = g(G_{\mathrm{NF}} + G_{\mathrm{NM}}) + \textit{random term}.$$

Also, applying simple regression analysis,

$$E_{\mathrm{NC16}} = k(Q_{\mathrm{NF}} + Q_{\mathrm{NM}}) + \textit{random term},$$

where

$$k = \frac{r(E_{\mathrm{NC}}, Q_{\mathrm{NP}})}{1 + r(\mathrm{F, M})} = \frac{\alpha Z}{e[1 + r(\mathrm{F, M})]}$$

(by Equation 22); that is,

$$\begin{aligned}2hes &= 2heE(G_{\mathrm{NC16}}, E_{\mathrm{NC16}})\\ &= 2heE[g(G_{\mathrm{NF}}+G_{\mathrm{NM}})k(Q_{\mathrm{NF}}+Q_{\mathrm{NM}})]\\ &= 2hegk2(h+es)[1+r(\mathrm{F, M})]\\ &= \frac{4\alpha Z}{1+r(\mathrm{F, M})}\{gh(h+es)[1+r(\mathrm{F, M})]\}\\ &= \frac{4\alpha Z}{1+r(\mathrm{F, M})}(Y_{16}-\alpha Z) \text{ by Explanation 5.}\end{aligned}$$

7. For foster child and natural mother (Equations 28 and 29),

$$\begin{aligned}&r(\mathrm{AC}x, \mathrm{NM}; \mathrm{SP})\\ &\quad = E[(h'G_{\mathrm{AC}x} + e'E_{\mathrm{AC}x})Q_{\mathrm{NM}}]\\ &\quad = (h/\alpha)r(G_{\mathrm{AC}x}, Q_{\mathrm{NM}}) + (e/\alpha)r(E_{\mathrm{AC}x}, Q_{\mathrm{NM}}).\end{aligned}$$

The first term on the right-hand side is $r(\mathrm{AC}x, \mathrm{NM}; \mathrm{NSP})$. From this, Equation 29 follows. Also,

$$\begin{aligned}r(E_{\mathrm{AC}x}, Q_{\mathrm{NM}}) &= r(E_{\mathrm{AC}x}, Q_{\mathrm{AM}})r(Q_{\mathrm{AM}}, Q_{\mathrm{NM}})\\ &= (\alpha Z/e)r(\mathrm{AM, NM})\end{aligned}$$

(Equation 22), making the usual assumption that selective placement takes place through matching of mothers. Hence,

$$(e/\alpha)r(E_{\mathrm{AC}x}, Q_{\mathrm{NM}}) = Zr(\mathrm{AM, NM}).$$

Male and Female Spoken Language Differences: Stereotypes and Evidence

Adelaide Haas
Department of Speech Communication
State University of New York College at New Paltz

Male speech and female speech have been observed to differ in their form, topic, content, and use. Early writers were largely introspective in their analyses; more recent work has begun to provide empirical evidence. Men may be more loquacious and directive; they use more nonstandard forms, talk more about sports, money, and business, and more frequently refer to time, space, quantity, destructive action, perceptual attributes, physical movements, and objects. Women are often more supportive, polite, and expressive, talk more about home and family, and use more words implying feeling, evaluation, interpretation, and psychological state. A comprehensive theory of "genderlect" must include information about linguistic features under a multiplicity of conditions.

Both casual and serious observers of the human condition have long recognized that communication between the sexes is often frustrating. A possible cause of the difficulty is that men and women may in fact not really be speaking the same language (Jong, 1977; Reik, 1954).

Aspects of form, topic, content, and use[1] of spoken language have been identified as sex associated. Either men or women are more likely to produce specific utterances. Informal observations, speculations, and stereotypes in each category are discussed first. This presentation is followed by a report of empirical findings[2] from a variety of communication situations. Although reports of stereotypes and evidence for male and female spoken language differences do not always coincide, they both contribute to one's understanding of sex roles and communication.

This review is based on a dissertation submitted to Teachers College, Columbia University in partial fulfillment of the requirements for the PhD degree. Deep appreciation is expressed to Edward Mysak, Lois Bloom, and Mary Parlee for their useful suggestions, criticism, and encouragement.

Requests for reprints should be sent to Adelaide Haas, Department of Speech Communication, State University of New York, New Paltz, New York 12562.

Form

> The form of utterances can be described in terms of their acoustic, phonetic shape . . . in terms of the units of sound, or *phonology*, the units of meaning that are words or inflections, or *morphology*, and the ways in which units of meaning are combined with one another, or *syntax*. (Bloom & Lahey, 1978, p. 15)

Perhaps the most widespread belief about men's speech as compared with women's is that it is coarser and more direct. An early observer of style in language, Jesperson (1922/1949), observed women's speech to be generally more conservative than men's in the following ways: Men are readier to coin and use new terms, pun, utter slang expressions, and employ profanity and obscenity. Women, on the other hand,

> are shy of mentioning certain parts of the human body and certain natural functions by the direct and often rude denominations which men and especially young men prefer when among themselves. Women will therefore invent innocent and euphe-

[1] The categories *form, topic, content,* and *use* were suggested by Lois Bloom of Teachers College, Columbia University and are described in Bloom and Lahey (1978).

[2] Mary Parlee of Barnard College, Columbia University suggested an evaluative review, separating stereotypes from empirical findings.

mistic words and paraphrases which sometimes may in the long run come to be looked upon as the plain or blunt names and therefore in their turn have to be avoided and replaced by more decent words. (p. 245)

Reik (1954) affirmed that "we all know that there is a 'man talk' and a 'woman talk'" (p. 14). He observed that "men . . . will not hesitate to say 'Hell' or 'Damned.' . . . Women will rarely say 'It stinks' preferring to state that it has a bad smell" (p. 14).

More recently, Kramer (1974b) quoted the following: "*The New Seventeen* on people who use 'those four letter words': Boys find it especially repugnant when girls use those words. One boy described girls who use profanity as having nothing better to say" (p. 22).

Lakoff (1973) observed that men use stronger expletives such as *shit* and *damn*, whereas women use weaker or softer profanity such as *oh dear*, *goodness*, or *fudge*. Farb (1974) suggested that *dear me* and *gracious* are part of the female lexicon, and Ritti (1973) stated that most teachers of the sixth grade are well aware that young girls use far more "expressives" such as *oh* and *wow* than do the boys in their classes.

Farb wrote, "Nowadays young women use words that were formerly taboo for them with as much freedom as young men use them" (p. 50), but young men are not permitted the more euphemistic expressions. However, research on people's perceptions of language as either male or female suggests that the earlier stereotypes of coarse, free male language contrasted with euphemistic female forms still hold. Garcia-Zamor (Note 1) asked four boys and four girls in an upper-middle-class nursery school to indicate whether certain utterances were produced by a male or female doll; *shit* was seen by both boys and girls as male, and *drat* was seen by both as female. In a study of adults' stereotypes, Kramer (1974a) asked college students to determine whether various captions taken from *New Yorker* cartoons were uttered by males or females. Men in the cartoons were found to swear more than women and for more trivial reasons.

A careful review of the literature revealed no empirical studies of the comparative use of expletives. Profanity and obscenity do not readily submit to laboratory study. Documentation of this stereotype would require recording speech of female-only, male-only, and mixed-sex groups in various settings. The speakers should certainly not know they are being observed.

Reports by individual investigators writing about their own experiences (Key, 1975; Lakoff, 1975) strongly suggest that the form of expressives is sex associated. A possible explanation is that expressives "serve different functions for men and women. Males use them when they are angry or exasperated. . . . But women's exclamations are likely to convey enthusiasm" (Kramer, 1974a, p. 83).

The form of women's language is reputed to be more polite than the form of men's. Lakoff (1975) noted that "women are supposed to be particularly careful to say 'please' and 'thank you' . . . a woman who fails at these tasks is apt to be in more trouble than a man who does so" (p. 55). She speculated that "the more one compounds a request, the more characteristic it is of women's speech" (p. 19). An example of a doubly compound request is "Won't you please close the door?" (p. 18).

Only one very limited empirical study of politeness forms was found: 16 women born in Maine around 1900 used more politeness forms than 12 male counterparts when interviewed by college students (Hartman, 1976).

According to Austin (1965), high, oral sounds and giggling sounds are appropriate for females in courtship, whereas males produce low and nasal sounds. Coser (1960) recorded verbal interactions involving humor at 20 staff meetings of a mental hospital. She found that senior staff members (psychiatrists) made more jokes than junior staff members (paramedics) and that men made more witticisms than women (99 out of 103), but women often laughed harder. Coser suggested that this concurs with the sex roles of male authority and female receptivity. Haas (1978) similarly found that girls laughed more than boys in mixed-sex dyads.

Women are permitted to cry, as reflected in Key's (1975) observation that "if a female talks or cries into a pillow it's 'muffled sobbing'; if a male does the same, it's 'blubbering,' with negative connotations" (p. 109). Crying has been observed more frequently in girls than in boys. In an analysis of 200 quarrels of preschool children, Dawe (1934) found that 35.8% of the girls cried compared with only 20.2% of the boys.

Several writers (Labov, 1966; Levine & Crockett, 1966; Trudgill, 1972) have speculated that men use more slang expressions than women or even that slang is man's domain. Conklin (Note 2), however, observed that women's vernacular has not been studied and suggested a need to especially examine the dialect of all-female groups. Empirical phonological studies of -in versus -ing endings (Fischer, 1958), of -uh versus -er endings (Levine & Crockett, 1966; Wolfram, 1969), and of f, t, and th usage (Wolfram, 1969), show black females more likely to use standard forms than black men. Similar results were found in studies of pronominal apposition, as in "my brother he went to the park," and multiple negation (Shuy, Wolfram, & Riley, 1968). Garvey and Dickstein (1972) noted more nonstandard forms in the speech of six dyads of boys from four population groups (black, white, and low and middle socioeconomic status) than in matched girls.

Joffe (1948) noted sex differences in the vernacular of menstruation, including the greater use of color references by men and of personification by women. For example, men might say "she's waving the red flag," whereas women might refer to "having my friend." This finding was part of a larger study in New York City on attitudes and beliefs about menstruation.

Jesperson (1922/1949) believed women leave sentences unfinished or dangling more often than men. In an informal survey of television panel discussions, Bernard (1972) noted that women are more frequently interrupted than men. This may help explain the unfinished sentences. No empirical evidence for sex differences in sentence completeness has been noted. Zimmerman and West (1975), however, reported in a study of 11 male–female dyads that "virtually all the interruptions and overlaps are by the male speakers (98% and 100% respectively)" (p. 115). They further noted that not one of the women who were interrupted protested. Similar results were reported by Eakins and Eakins (1976).

Women have long had the reputation for being more loquacious than men: *"Où femme il y a, silence il n'y a"* (Where there's woman, there's no silence.) "The tongue is the sword of a woman, and she never lets it become rusty" (China). "The North Sea will sooner be found wanting in water than a woman at a loss for a word" (Jutland; cited in Jesperson, 1922/1949, p. 253). Jesperson believed that

> the superior readiness of speech of women is a concomitant of the fact that their vocabulary is smaller than that of men. But this again is connected with another indubitable fact, that women do not reach the same extreme points as men, but are nearer the average in most respects. (p. 253)

He gave many examples of how women are supposed to talk ahead of thinking, to talk more than men.

Lakoff (1975) informally observed longer sentence forms in women than in men, possibly resulting in the impression of more speech. For example, women are more likely to compound a request: "Will you help me with these groceries, please?" is more characteristic of women than "Help me" or even "Please help me with these groceries." Empirical evidence, however, suggests that at least under certain conditions women's sentences are shorter than men's. For example, at professional conferences, the mean time used by women asking a question was reported to be less than half that used by men (Swacker, 1975).

Studies of sex differences in length of utterance in children indicate that girls are significantly superior to boys at various matched age levels in mean length of utterance (Winitz, 1959). Maccoby (1966, p. 335) reported similar results in her summary of 19 studies. Garvey and Ben Debba (1974), however, found no sex differences in words per utterance among same-sex or mixed-sex dyads ranging in age from $3\frac{1}{2}$ to $5\frac{3}{4}$ years

and participating in free-play testing situations. In considering mean length of utterance of children, language maturation must be considered a factor, since utterances normally become longer as skill in language increases and most studies show that girls develop language facility earlier than boys. Limited evidence, then, suggests that although in early childhood female sentences are longer than those of males, by adulthood the reverse may be true.

Mixed results have been reported in studies of verbosity (Maccoby, 1966, p. 335). In a task involving adults' responses to picture stimuli, Wood (1966) concluded that men tend to use more words than women in responding to a given stimulus. Like results in similar situations were found by Argyle, Lalljee, and Cook (1968) and Swacker (1975). Cherry's (Note 3) review of 11 studies dealing with children's quantity of speech reported that girls tended to exceed boys in this dimension in 6 of the studies. No differences were noted in 4 studies.

The participants in a communication influence quantity of verbalization. In mixed-sex groups, men tend to talk more than women (Argyle et al., 1968; Bernard, 1972).

Among children the composition of the communication group also seems to affect verbosity. Mueller (1972), in a study of "the maintenance of verbal exchanges between young children" (ages 3½–5 years) found that "boys talked significantly more than girls" (p. 933) in a free-play situation to same-sex peers. Brownell and Smith (1973), however, reported more verbal productivity among 4-year-old girls in comparison with same-age boys in mixed-sex dyads, triads, and small groups. In preschool children, then, boys have been found to talk more to boys and girls to talk more in mixed-sex groups—the reverse of the adult pattern.

Entwisle and Garvey (1972) reported sex differences in verbal productivity among Baltimore children, with girls more productive than boys; note that this finding is most marked among those of lower social class. Possibly no real difference exists in the quantity of talk that is produced by men and women, but "girls are not *supposed* to talk as much as a man" (Kramer, 1974b, p. 17).

In sum, the stereotype clearly shows women to be more verbose than men. Empirical evidence is mixed. Girls seem to talk somewhat more than boys, but adult women, especially in the company of men, have been found to talk less than their male companions.

Topic

Topic refers to the subject matter of the spoken utterance, to what the conversation is about.

Kramer (1974b) captured much of the folklore related to topics of male and female conversations through her study based on *New Yorker* cartoons:

> Men hold forth with authority on business, politics, legal matters, taxes, age, household expenses, electronic bugging, church collections, kissing, baseball, human relations, health and—women's speech. Women discuss social life, books, food and drink, pornography, life's troubles, caring for a husband, social work, age, and life-style. Several of the students who rated the cartoon captions said they considered all statements about economics, business or jobs to be male. (p. 83)

The interviews by Komarovsky (1967) suggest similar stereotypes in blue-collar families. One 28-year-old wife commented that "[men] think we [women] are silly and talk too much. They think that women gossip a lot and they are against it" (p. 150). A 36-year-old husband noted that women want "to talk about kidstuff and trivia like Mrs. X had her tooth pulled out" (p. 150). Women reported that they enjoyed talking about the family and social problems. Both sexes acknowledged that men prefer to talk about cars, sports, work, motorcycles, and local politics.

Klein's (1971) observations of the working class in England are similar:

> Just as men in the clubs talk mainly about their work and secondly about sport and *never* about their homes and families, so do their wives talk first of all about *their* work, i.e.: their homes and families, and secondly within the range of things with which they are all immediately familiar. (p. 73)

In mixed-sex conversations the impression is that women initiate topics that are rarely followed through by men (Bernard, 1972; Chesler, 1972).

Three studies in the 1920s of conversational topics using tape-recorded fragments of conversations on city streets are of interest. Moore (1922) recorded 174 conversations in New York City and reported that man-to-man topics included money and business (48%), amusements or sports (14%), and other men (13%). Woman-to-woman topics were men (44%), clothing or decoration (23%), and other women (16%). Male-to-female topics were amusements or sports (25%) and money and business (22%). Women talked to men about other men (22%) and other women (13%).

M. H. Landis and Burtt (1924) conducted a similar study in Columbus, Ohio and recorded 481 conversations. Their findings concur with Moore's. Men talked to men about business and money 49% of the time, sports or amusements 15% of the time, and other men 13% of the time. Women talked to women about men (22%), clothing or decoration (19%), and other women (15%). Women talked about people in 37% of the conversations. Man-to-woman topics included amusement and sports (25%), money and business (19%), and themselves (23%). Women talked to men about amusements or sports (24%), clothing or decoration (17%), and themselves (17%).

In 1927, C. Landis analyzed 200 London conversations. The all-male topics were similar to those in New York City and Columbus, but the women talked about a wider variety of topics among themselves. Landis suggested that in mixed-sex conversations, "the Englishman when talking to a feminine companion adapts his conversation to her interests while American women adapt their conversations to the interests of their masculine companions" (p. 357).

In a study of "the women of the telephone company," Langer (1970a, 1970b) reported that men discussed politics among themselves, whereas women avoided religion and politics in their conversations.

Mulcahy (1973), using a self-disclosure questionnaire with 97 adolescents, reported that female same-sex disclosure was greater than male same-sex disclosure. Major topics for girls were "tastes, interests, and personality" (p. 343); for boys high disclosure clustered about "tastes, and interests, work (studies), and attitudes and opinions" (p. 343). "The lowest disclosure area for males was Body, whereas it was Money for females" (p. 354).

Sause (1976) reported that kindergarten girls made more reference to the female role than did kindergarten boys, and this was the only category that girls referred to more than boys in this study of 144 subjects. Boys talked more about family and home environment, recreation, other people, and animals, but the differences were not significant. Utterances were all to a male examiner who encouraged the children to talk about two stimulus objects—an irregularly shaped block and a toy fire engine.

Knowledge of conversational topics is limited. Although the evidence supports the stereotype that women talk more about people and men more about money, business, and politics, the studies date back to the 1920s. Times have been changing!

Content

Content refers to the "categorization of the topics that are encoded in messages," such as "object in general," "actions in general," and the "possession relation in general" (Bloom & Lahey, 1978, p. 11). Content differs from topic, since topic refers to particular objects, events, and ideas, whereas content refers to the more general concept of how the topic is referenced.

Women's language is more emotional and evaluative than men's according to the stereotype (Jesperson, 1922/1949; Kramer, 1974a; Lakoff, 1975; Pei, 1969; Reik, 1954). Jesperson wrote of women's fondness for hyperbole and their greater use of adverbs of intensity such as *awful, pretty, terribly nice, quite,* and *so.* These all suggest value judgments. Reik believed terms such as *darling, divine, sweet, adorable, I could just scream,*

I nearly fainted, and *I died laughing* are female associated. Pei observed "extravagant adjectives" such as *wonderful, heavenly, divine*, and *dreamy* in women's speech. Again the focus is on emotional value judgment.

Lakoff's (1975) list of female adjectives includes *adorable, charming, lovely*, and *divine*. Male adjectives are *great, terrific* and *neat*. Kramer (1974a) suggested that "words of approval" (p. 22) such as *nice, pretty, darling, charming, sweet, lovely, cute*, and *precious* are used more frequently by women.

Hartman (1976) tested and supported Lakoff's hypothesis that women use evaluative adjectives more than men. In her study of 70-year-old native Maine men and women, she found that women compared with men used many more words such as *lovely, delightful, wonderful, nice, pretty, pathetic, pretty little, smartly uniformed, cute, dearest, gentle, gaily, beautifully, lovelies, very very, devoted, meek, perfectly wonderful*, and *stylish*. Most women used *awful* and *pretty* to mean *very* and *so*.

Wood (1966) analyzed the speech of 36 college students (18 men and 18 women) as they described photographs of a man's face. She found that males referred more directly to what was actually in the picture. Females were more interpretative and tended to be more subjective in their descriptions. Barron's (1971) study of speech by teachers and pupils during regular classroom activities showed patterns similar to those reported by Wood. Through an analysis of the grammatical cases of speaker's utterances, Barron found that women used more participative and purposive cases and men used more instrumental and objective cases. Specifically, women talked more about how people felt and why they behaved in certain ways. Men's speech focused more on objects and actions related to these objects.

Gleser, Gottschalk, and Watkins (1959) studied the speech of 90 white adult men and women who were asked by a male examiner to tell about "any interesting or dramatic life experiences you have had" (p. 183). As did the other studies, this investigation revealed that women used significantly more words implying feeling, emotion, or motivation (whether positive, negative, or neutral); they made more self-references and used more auxiliary words and negations. Male subjects referred more to time, space, quantity, and destructive action. This can be viewed as supporting Eble's (Note 4) suggestion that terms of hostility are more associated with men.

Physical movement was more frequently referenced by kindergarten boys than by girls (Sause, 1976). Boys also used significantly more words classified as self, space, quantity, good, bad, and negative words. Garcia and Frosch (1976) also found that males talked more about spatial relations than females. Their subjects were 40 black, Anglo, and Spanish-speaking adults, ranging in age from 18 to 65 years, who were asked to respond to two pictures (one "female room" and one "male outdoors scene") from current magazines. Females described items in terms of patterns and colors more than did males. Also of interest was the observation that "each [sex] group went into immediate detail when describing the visual which was stereotyped to their sex group, but paused to 'orient themselves' to the environment when approaching the other visual" (p. 68).

Comparative use of adjectives was studied by Kramer (1974b), Brandis and Henderson (1970), and Entwisle and Garvey (1972). College students writing descriptions of black and white photographs did not differ in the type or number of prenominal adjectives used or in the number or variety of -ly adverbs (Kramer, 1974b). However, according to the studies by Brandis and Henderson and Entwisle and Garvey, girls use more adjectives than boys. The Brandis and Henderson study was on spoken language by 5-year-old working-class British children; the Entwisle and Garvey study was based on the written language of ninth graders when asked to write imaginative stories after viewing four stimulus pictures.

Garvey and Dickstein (1972) found that fifth-grade black and white boys of low and middle socioeconomic status used the possessive construction more frequently than females of the same age, race, and socioeco-

nomic status during oral communication involving problem-solving tasks.

The stereotype of the content of spoken language, then, points to positive value judgments as female marked and hostile judgments as male marked. The empirical evidence suggests that the content of adult female speech includes more words implying feeling, auxiliary words, negations, evaluative adjectives, interpretations, psychological state verbs, and purposive cases. Adult males use more terms referring to time, space, quantity, destructive action, and perceptual attributes and more objective cases. Boys have been reported to use more words related to self, space, quantity, good, bad, negation, and possession. It is likely that girls use more adjectives. Studies of adult use of adjectives show mixed results.

Use

"Language use consists of the socially and cognitively determined selection of behaviors according to the goals of the speaker and the context of the situation" (Bloom & Lahey, 1978, p. 20).

Bernard (1972) suggested that "instrumental" talk is male associated. Men are stereotyped as the conveyors of information and fact. Women "tend to be handicapped in fact-anchored talk. . . . They are . . . less likely to have a hard, factual background, less in contact with the world of knowledge" (p. 153). The male instrumental style includes lecturing, argument, and debate. This has not been empirically documented to date.

Assertiveness was observed as part of the male stereotype by Kramer (1974b) in her study of cartoon captions. Lakoff (1975) suggested that women's speech is nonassertive. This concept has been developed by other writers. Kuykendall (Note 5) wrote that "clean, effective vigorous speech and writing is just what women, *qua* women, learn not to produce so as not to appear too assertive and so to offend" (p. 4). Furthermore, "Assertion of competence and power by a female is regarded as deviant behavior so that she becomes the recipient of social sanctions" (Unger, Note 6, p. 43). Wolman and Frank (1975) observed that in a professional peer group a woman was labeled *bitchy* or *manipulative* when her behavior was assertive and directive. Nursery school children also believe that competitive and aggressive language is appropriate for males only, as demonstrated by a study in which boys and girls were asked to ascribe various uttered sentences to a girl or boy doll (Garcia-Zamor, Note 1). Dawe (1934) found that when nursery school children quarreled, boys were assertive by threatening and forbidding more often than girls.

Tentativeness has been stereotyped as female. Lakoff (1975) suggested that tag questions (e.g., "It's cold, isn't it?") are used far more often by women than by men. This form of question avoids assertion and gives the addressee the option of agreeing or disagreeing. Women's speech is said to be "hedge marked."

Empirical evidence is mixed. Hartman (1976) reported that tentativeness was clearly female associated among the 70-year-old Maine natives whose speech she studied. This was revealed in the women's greater production of qualifiers such as *perhaps, I suppose, I just feel, probably,* and *as I interpret it* and tag questions such as "Well, most people would say marriage, wouldn't they?" and "It was grandmother, wasn't it?" Swacker (1975) found that female college students indicated approximation when using numbers ("about six books"), whereas only one male used the tentative form in a task requiring the description of three pictures by Albrecht Dürer. However, in dyadic conversations of college students, Hirschman (Note 7) found no difference between the sexes in the overall proportion of qualifiers such as *maybe, probably, I think,* and *I guess.* In a somewhat larger study, Hirschman (Note 8) found that males uttered *I think* twice as much as females. (*I think* is usually considered a qualifier, but Hirschman suggested that it served primarily as a way for more assertive speakers to present their opinions.) Loban (Note 9) reported that expressions of tentativeness including supposition, hypothesis, and conditionality are associated with effective users of language from

kindergarten through sixth grade. Hass and Wepman (1973) similarly found that uncertainty increased as a function of age in children 5 to 13 years old and noted that "there are many fine points about the uncertainty scores [with regard to the Age × Sex interaction] that demand further investigation" (p. 305). Baumann (1976) analyzed 7½ hours of tape of adults in various settings for confirmatory tag questions and qualifying prefatory statements. She found only 20 examples altogether and no sex-associated use.

Men and women may make requests in different ways. Lakoff (1975) observed that women state requests and men issue commands. Hennessee and Nicholson (1972) reported that in over 1,000 television commercials, men gave almost 90% of the directives, that is, the advice or commands to buy a particular product. In a naturalistic study of the conversations of a single married couple, Soskin and John (1963) reported that the husband gave far more directives than the wife. In one critical situation when they were rowing and the boat capsized, mainly the husband gave regulative statements such as demands, suggestions, and prohibitions.

Hirschman (Note 8) tested the hypothesis that women are more supportive than men. No overall differences were found between the college men and college women studied, although females used 'mm hmm" significantly more than males and most of these utterances occurred in female-to-female conversations. In mock jury deliberations, Strodtbeck and Mann (1956) reported that women agreed, concurred, complied, accepted, and supported other speakers almost twice as much as men did. Similarly, women were antagonistic or offensive half as often as men. Conversely, men were more assertive. Supportive behavior can be inferred from the emotional sensitivity Alvy (1973) reported to be more characteristic of grade-school girls than of boys of lower, middle and upper socioeconomic status in an experiment of listener-adapted communication.

In use, then, men's speech reputedly serves to lecture, argue, debate, assert, and command. Women's speech is stereotyped as nonassertive, tentative, and supportive. Limited evidence confirms that males are more assertive and issue more directives; females are often more tentative and supportive.

Conclusions and Implications

Do male and female spoken language differences exist? The stereotypes abound, and evidence has been accumulating, especially since the beginning of this decade.

Women's speech is said to contain more euphemisms, politeness forms, apology, laughter, crying, and unfinished sentences. They are reputed to talk more about home and family and to be more emotional and positively evaluative. Further, women's speech is stereotyped as nonassertive, tentative, and supportive. Women are also said to talk more than men.

Men, on the other hand, are reputed to use more slang, profanity, and obscenity and to talk more about sports, money, and business. They are reputed to make more hostile judgments and to use language to lecture, argue, debate, assert, and command.

Empirical evidence is less clear, partly because studies can only sample limited populations in specific situations. Further, sex differences in American English are only statistical differences. No feature of spoken American English is used exclusively by one sex or the other. In general, however, empirical studies of form confirm that males use more nonstandard forms than females and that females laugh and cry more. Older Maine women, at least, are more polite, and sixth-grade girls claim they use more expressives. Contrary to the stereotype, adult men have been found to be more loquacious, but it is unclear whether boys or girls are more verbose. Studies from the 1920s support the stereotype that men talk more about money, business, and politics and that women talk more about home and family. The empirical evidence supports the stereotype of content differences in men's and women's speech. Various studies found that women use more emotional language and men focus more on perceptual attributes and destructive action. The males studied were generally

more assertive and directive than the women. One study found that women are more supportive than men, and the results of research on tentativeness are mixed.

Are these isolated, unrelated variations in speech, or is there a logical clustering that points to "systems of co-occurring, sex-linked signals," or "genderlects," as Kramer (1974b, p. 14) proposed?

If, in fact, one can say that there is a male speech style and a female speech style, then rules and restrictions can be written for each much in the way that grammatical structures are described. This task is complicated by two major observations: (a) Sex differences in spoken language that have been identified in English are sex preferential as opposed to sex exclusive (Bodine, 1975); that is, there is no evidence that any linguistic feature is used exclusively by one sex in our society; variations have been found only in frequency of production. (b) Sex is not the only variable to influence speech style. There is a complex interaction of personal characteristics such as sex, age, education, occupation, geographical region, ethnic background, and socioeconomic status and contextual factors such as communication, situation, environment, and participants.

Despite these complications, a start has been made at constructing a grammar of style for men's and women's language (Lakoff, Note 10). Lakoff focused on women's style and suggested that it is basically one of deference. She suggested that the various phonological and lexical forms and the syntactic–pragmatic features identified as occurring more often in women's speech add up to a pattern of deference. However, deference alone does not make a woman's style. Other characteristics of the individual and the context combine to form the complete style. Lakoff pointed to a need to learn which styles can coexist and which cannot. Even more important is the need to know which sex-associated spoken language features are real and to document conditions under which they occur.

Communication can be viewed as a microcosm of social behavior. Much of human interaction occurs at the linguistic level. As Gumperz and Hymes (1972) pointed out,

> If sociolinguistic research often begins as an extension of linguistics, it must end as an intension of the social sciences—but in the idiom of disciplines that is only to say that it changes from a way of studying language to a way of studying man as a social being. (p. 466)

The stereotypes and evidence discussed in this article have significant implications for the power structure between the sexes and indeed the psyche of both men and women. Future researchers need to be sensitive to situations in which they observe sex-associated speech and to be cautious of making premature judgments. In any event, there is little doubt that recent interest in gender and language will continue to generate worthwhile exploration into this topic. Clinicians and theoreticians alike will thereby increase their understanding of this important dimension of human communication.

Habituation Model of Systematic Desensitization

Fraser N. Watts
King's College Hospital
University of London, London, England

The relevance of habituation as a model for response decrement in desensitization is considered. A discussion of the relationship between habituation and extinction leads to the view that there are no sound reasons for explaining desensitization as an extinction rather than as a habituation phenomenon. The maximal habituation theory of desensitization proposed by Lader and Mathews is discussed and relevant evidence reviewed. Finally, a revised habituation theory of desensitization, based on the dual-process theory of habituation, is elaborated, and the role in desensitization of relaxation, stimulus intensity, stimulus lengths, and interstimulus interval lengths are discussed in the context of this theory. It is suggested that relaxation and an incremental stimulus hierarchy may reduce sensitization rather than facilitate habituation.

More than 10 years ago, Lader and Wing (1966) proposed a habituation theory of desensitization. The theory was subsequently elaborated by Lader and Mathews (1968) and has become known as the *maximal habituation* theory of desensitization. Though it has not won general acceptance, it has stimulated a significant body of research and has increased our knowledge about the processes at work in desensitization. It has thus passed at least one test of a useful theory. However, it is now clear that this version of the habituation theory of densensitization has a number of weaknesses. It is the purpose of this article to review relevant research and to elaborate a reformulation of the habituation theory of desensitization in the light of the dual-process habituation theory (Groves & Thompson, 1970) that has been developed since the maximal habituation theory of desensitization was proposed.

Desensitization: Habituation or Extinction?

Habituation can be defined as the waning of a response to a stimulus that occurs when the stimulus is repeatedly presented. It is usually said to be a central nervous system process, which distinguishes it from other decremental processes such as fatigue. It is also said to apply only to the decrement of unconditioned responses. This distinguishes it from extinction, which applies to conditioned responses. Though the habituation of a wide variety of responses has been described in the literature, the most extensively investigated has been the habituation of the orienting response to a repeated auditory stimulus. At first sight it may seem surprising that a habituation rather than an extinction model of desensitization should be under discussion (Evans, 1973), and the first task of a review of the habituation model must be to deal with this question.

If habituation applies to unconditioned responses and extinction to conditioned responses, the question of whether desensitization should be termed a habituation or an extinction process can be settled by definition on the basis of whether the responses being modified in desensitization are conditioned or unconditioned. However, the approach taken here is an empirical one, to see what empirical differences exist between habituation and extinction and whether the decremental processes that operate in desensitization are more closely analogous to

those found in habituation or to those found in extinction.

The most widely canvassed empirical difference between the two is that habituation is a short-term or temporary change in responsiveness, whereas extinction is a long-term or permanent one. Van Egeren (1971) has even suggested that this should be the defining distinction between habituation and extinction. However, such a proposal involves attaching a new meaning to the term habituation in view of the fact, acknowledged by Van Egeren, that the decrement of the orienting response on repetition of a stimulus can sometimes be relatively long-term. Though habituation may often be a relatively short-term process, it seems that unconditioned responses do not always show shorter term decrements than conditioned ones. Kimmel (1973), in a discussion of the differences between habituation and conditioning, reached the parallel conclusion that "habituation cannot be differentiated from conditioning simply on grounds of its temporariness" (p. 229).

It has been suggested by Razran (1971, p. 30) that habituation, unlike extinction, is not affected by cognition. However, this view of habituation seems to be incorrect. The rate of habituation is certainly modified by instructions that affect the set with which subjects approach stimuli (e.g., Pendergrass & Kimmel, 1968).

Another possible difference between the processes of habituation and those of extinction is that extinction produces a stimulus with response-suppressant properties but habituation does not. The crucial test of response suppression (Rescorla, 1969) is the summation test. If a stimulus has acquired response-suppressant properties as a result of habituation or extinction, when it is subsequently combined with a separate conditioned stimulus, it should produce a smaller response than the conditioned stimulus would produce on its own. Reiss and Wagner (1972) have shown that by this test habituation does not give response-suppressant properties to the stimulus concerned. If it were well established that extinction does indeed give a stimulus such properties, there would be a good reason for regarding habituation and extinction as different processes. However, the evidence on this point (Gray, 1975, pp. 105–106; Rescorla, 1969) is weak and so fails to establish a critical difference between the processes of habituation and extinction.

A number of other similarities and differences between habituation and extinction have been investigated. It is known that stimulant drugs retard both processes (Hilgard & Marquis, 1940; Lynn, 1966). In addition, temporal massing of stimuli normally facilitates both processes (Kling & Stevenson, 1970). Among differences that have been reported, Kling and Stevenson found that extinction produced an initial increase in responsiveness, though habituation did not. However, until such differences are replicated and their theoretical significance clarified, they can hardly provide an adequate empirical basis for concluding that different processes are involved in habituation and extinction. It can thus be concluded that no reliable empirical differences have been established between extinction and habituation on which the question of which process operates in desensitization could be settled. Thus, at present, it seems reasonable to use either habituation or extinction as a model for desensitization.

However, there are some general theoretical grounds for suggesting that the habituation of orienting responses may prove a particularly useful analogue for the decrement of anxiety in desensitization. They depend on the argument advanced by Gray (1975, 1976) that both novel stimuli that elicit orienting responses and stimuli that have been paired with punishing stimuli and arouse anxiety activate what Gray described as the "behavioural inhibition" system. This system produces an inhibition of ongoing behavior and increases arousal (though it does not produce the kind of response-suppressant effect measured by the summation test). Sedative drugs decrease the level of operation of the system. It is also relevant to note that this behavioral inhibition system has been found to be particularly active in neurotic introverts (Nicholson & Gray,

1972), who are also the personality group of which phobics are largely composed (Marks, 1969). So if it is correct that aversive stimuli and novel stimuli activate the same physiological–behavioral system, it seems reasonable to suggest that the processes of response decrement to both kinds of stimuli are similar. There is thus some reason for thinking that the habituation of orienting responses is worth pursuing as an analogue of response decrement in systematic desensitization.

Maximal Habituation Theory

The clearest available statement of the habituation model of desensitization is the maximal habituation hypothesis proposed by Lader and his colleagues (Lader & Mathews, 1968; Lader & Wing, 1966). The basic postulates of the model are that the rate of observed reduction in the magnitude of the galvanic skin response (GSR) to repeated presentations of phobic situations is a habituation process and that this habituation process is maximized by aspects of the procedure (notably relaxation) that lower central arousal (measured in terms of spontaneous GSR fluctuations). The model focuses entirely on the rate of response decrement as the dependent variable (measured as the slope of the linear decremental trend corrected for initial response levels). It is assumed that increasing the rate of response decrement in desensitization makes it a more effective treatment in the long term.

Individual Differences

The analogy between desensitization and habituation is supported by data on individual differences. Lader, Gelder, & Marks (1967) found a significant (.49) correlation across subjects between the rate of auditory habituation and clinical response to desensitization. In addition Lader (1967) showed that specific phobics exhibited both faster auditory habituation and a better clinical response to desensitization than other phobics.

These initial reports were followed by several similar studies. The most directly comparable study is that reported by Gillan and Rachman (1974), which failed to find a significant correlation between the same two measures. However, the number of subjects who received desensitization (16) was too small for this result to be given much weight. In addition, the correlation may have been lowered by the use of an experimental design that necessitated the omission of relaxation from the desensitization of half these subjects. Klorman (1974) also found a nonsignificant correlation between the rate of GSR decrement in auditory habituation and fear change after exposure to films of phobic stimuli, though the pattern of exposure of these films did not follow standard desensitization practice. Lang (1970), using a similar film exposure procedure in a complicated and somewhat incompletely reported experiment, has provided evidence that supports Lader et al.'s original finding. The rate of GSR habituation to tones of 50 dB and 100 dB correlated significantly with fear change as a result of the standard form of desensitization that includes relaxation. (The correlations were apparently low or insignificant when relaxation was omitted.) A number of significant correlations were also found between rate of GSR decrement to auditory tones and rate of decrement to phobic stimuli (Lang, 1970, p. 153), though there were too many insignificant correlations for the results as a whole to be convincing. In addition, the interpretation of this study is seriously affected by the fact that the rate of decrement to phobic stimuli did not correlate significantly with treatment outcome. This means that the relationship between treatment outcome and habituation rate to auditory stimuli was not mediated by the rate of anxiety decrement in desensitization. Instead of habituation rate directly influencing treatment outcome, it is more likely that both were a product of some other variable such as general arousal and that the specific mechanism relating arousal to outcome is something other than habituation rate.

All the above studies were concerned with GSR habituation, though heart-rate decrement has also been examined. Lang, Melamed and Hart (1970) reported a very high

correlation (.91) between heart rate decrement during desensitization and treatment outcome. However, Van Egeren (1970) found that the correlation between habituation rate to phobic versus neutral stimuli held only for skin conductance and not for heart rate and other variables. The explanation of such discrepancies between outcome indices can partly be explained in terms of their differential sensitivity at different arousal levels. As Lader (1975) has pointed out, the GSR is more sensitive at lower and heart rate at higher levels of arousal.

So far the support for the habituation model from studies of individual differences has been weak and inconsistent. However, the results should not be taken as counting strongly against the model. The proposition under consideration is that there are similar response decrement processes at work in auditory habituation and systematic desensitization. It seems to be a general feature of psychology that outcome measures in two different response systems can be the result of similar processes and that these measures correlate only weakly across subjects. Shapiro (1966) has put this forward as a general proposition, giving as one example that there can be low correlations across subjects between the strengths of different conditioned responses (GSR, eyeblink, etc.), but nevertheless in both cases the conditioned responses are affected by the same variables, such as frequency of reinforcement. In the same way, response decrement in auditory habituation and systematic desensitization could be the result of similar processes, without the degree of decrement found in these two situations necessarily being highly correlated across individuals.

Relaxation

Reciprocal inhibition theory (Wolpe, 1958) sees the role of relaxation training in desensitization as producing a state of muscular relaxation incompatible with the state of anxiety usually elicited by phobic stimuli. This state of reciprocal inhibition is turned, by reinforcement, into a more permanent state of conditioned inhibition. In contrast, the maximal habituation model (Lader & Mathews, 1968) views the role of relaxation as lowering central arousal (measured by spontaneous GSR fluctuations). This in turn increases the rate of response decrement.

In support of this view, Mathews and Gelder (1969) showed that relaxation does indeed reduce the frequency of spontaneous GSR fluctuations. In addition, Lader and Wing (1966) showed that sedatives had a similar effect and also resulted in a faster rate of GSR decrement to auditory stimuli. It thus seems reasonable to suppose that the arousal-lowering effect of relaxation has a similar effect on the rate of response decrement in systematic desensitization. Subsequent evidence has generally supported the view that relaxation lowers arousal, though relaxation is apparently not a uniquely effective procedure for achieving this result. The results of experiments that examine its effects therefore depend on what control procedure relaxation is compared with. Relaxation produces lower levels of arousal than attention to instructions (Mathews & Gelder, 1969), than an "eyes-open" control condition (Teasdale, 1971), or than looking at a neutral slide (Benjamin, Marks, & Huson, 1972), but is not more effective than procedures that simply omit Jacobsonian muscular relaxation exercises but that would in other respects be equally likely to induce a state of lowered arousal (Edelman, 1971; Grossberg, Note 1).

Support for the assumption that relaxation increases the rate of response decrement in desensitization has been weaker. There is some supporting evidence from Van Egeren (1971) and Wolpe and Flood (1970), though others (Benjamin et al., 1972; Waters & McDonald, 1973; Waters, McDonald, & Koresko, 1972) have reported negative results. One of the problems in interpreting some of these results is that relaxation seems to result in increased responsiveness to the initial presentation of a phobic stimulus. For example, that Wolpe and Flood (1970) reported response decrement with relaxation, but not without it, seems to be entirely attributable to the larger initial responses in the relaxation condition. There is also some

doubt about whether relaxation produces faster decrement of subjective anxiety. Waters et al. (1972) reported that subjects reached the criterion of no subjective anxiety in fewer trials with relaxation, but Benjamin et al. (1972) found no differences in subjective anxiety decrement between a relaxed and a nonrelaxed condition.

It is even more doubtful whether relaxation facilitates response decrement in auditory habituation. Lader and Mathews (1968) had no relevant evidence at the time they published their theory. However, this was subsequently investigated by Teasdale (1971) in a series of four experiments, using tones of 70 dB and 92 dB. He found no effect of relaxation on the rate of response decrement. In addition, Freeling (1972) reported that relaxation did not increase response decrement to a series of pistol shots. The assumption that relaxation increases the rate of response decrement has thus received only very weak support, and it is doubtful whether a version of the habituation model that has the effect of relaxation as a central assumption can be maintained. However, an alternative version of the habituation model of desensitization is elaborated in the remainder of this article, which does not assume a direct effect of relaxation on the habituation process.

Dual-Process Habituation Theory

So far the term *habituation* has been used to refer to an observable process of response decrement, but the recent development of dual-process habituation theory (Groves & Thompson, 1970; Thompson, Groves, Teyler, & Roemer, 1973) makes it necessary to clarify this usage. Dual-process theory proposes that observable response decrement is the summation of two inferred processes; habituation and sensitization. Response increment is equally the summation of the same two inferred processes.

It is not obvious that sensitization is a good term for the process of incremental change in responsiveness to a repeated unconditioned stimulus that Groves and Thompson referred to. The term already has a different technical meaning in the context of conditioning theory (e.g., Kimble, 1961), but it seems that even more confusion would be caused by adopting a different term in the present article.

Habituation and sensitization are most conveniently defined by contrasting their characteristics:

1. Habituation is a purely decremental process, whereas sensitization at first grows and then decays.
2. Habituation affects a particular response to a particular stimulus, whereas sensitization affects general responsiveness.
3. Habituation is independent of stimulus intensity (Thompson et al., 1973), whereas sensitization is positively related to stimulus intensity.
4. Though both habituation and sensitization decay spontaneously, sensitization is the more transient phenomenon (Davis, 1972).
5. Repeated series of habituation training trials result in progressively more habituation but in progressively less sensitization.

Groves and Thompson's theory resembles the conclusions reached by Hinde (1966) about change in responsiveness on the basis of his review of the relevant ethological research. Hinde also found it necessary to postulate an incremental process that accompanies the decremental one. There is also agreement that the decremental process is relatively stimulus specific and that the incremental process is a generalized one.

It is clear that response increment can result from exposure to a phobic stimulus. For example, Miller and Levis (1971) gave snake-phobic subjects two avoidance tests separated by a 50-minute interval. There were four experimental groups who spent respectively 0, 15, 30, and 45 minutes of this time in visual observation of the snake. The no-exposure group showed the least avoidance behavior during the second test (and significantly less avoidance than the 15-minute-exposure group). This indicates that exposure activated an incremental process. For the three groups that received some degree of exposure to the snake between tests, there was a tendency for the amount of exposure to be negatively associated with

avoidance behavior during the second test. Stone and Borkovec (1975) obtained similar results. The no-snake-exposure and the 45-minute-snake-exposure groups showed less avoidance behavior and autonomic arousal during the postexposure test than did the 15-minute-exposure group. The greater responsivenes of the 15-minute than the no-exposure group during the posttest indicates the presence of some kind of incremental process, whereas that this increased responsiveness was not found in the 45-minute-exposure group is consistent with the decay of sensitization over this period.

Relaxation

The maximal habituation theory (Lader & Mathews, 1968) proposes that the role of relaxation in desensitization is to lower arousal and that this in turn facilitates the rate of habituation. Dual-process theory invites a different view, namely, that relaxation reduces the amount of sensitization that takes place. Relaxation may not affect habituation at all, but its effects on sensitization summate with the habituation process to inrease the rate of response decrement.

As sensitization is a relatively transient process, the facilitatory effect of relaxation on response decrement would be only short-term. It is relevant in this connection to note that Teasdale (1971) found that relaxation had no immediate effect on auditory habituation, but resulted in less long-term decrement. Whether relaxation reduces the amount of long-term anxiety reduction in desensitization also is not clear. One problem in examining this is that an avoidance test given immediately after treatment would affect performance during a subsequent avoidance test. Subjects who received desensitization with relaxation might do better at follow-up simply because they had done better at an immediate posttreatment test and this had had an anxiety-reducing effect. It would therefore be necessary to use a design in which different subjects were used for testing the immediate and the delayed effects of relaxation on response decrement in desensitization.

Stimulus Intensity

It has been shown that the use of a graded incremental stimulus hierarchy facilitates response decrement to repeated auditory stimuli (Davis & Wagner, 1969; Groves & Thompson, 1970), and this has been attributed, in the context of dual-process theory, to the minimization of sensitization rather than to the maximization of habituation. Dual-process theory also proposes that the value of a graded hierarchy in desensitization, like that of relaxation, is to minimize sensitization. If this is correct, it implies, as Davis (1972) pointed out, that the beneficial effects of an incremental hierarchy would be relatively transient and might not appear on delayed testing. That Krapfl and Nawas (1970) found that the use of a graded hierarchy in desensitization was no more beneficial during testing immediately after treatment than during the follow-up counts against this view. However, the superiority of a graded hierarchy in the short term is more likely to appear with severely handicapped phobics. Krapfl and Nawas's experiment, like many others, used student snake phobics. In addition, as with the effects of relaxation, the immediate and long-term effect of a graded hierarchy should be tested in different subjects. Two other experiments (Klorman, 1974; Lang, 1970) that also failed to find a short-term advantage in an incremental hierarchy cannot be given much weight, as they used only two or three different intensity levels. Davis and Wagner (1969) showed for auditory habituation that a hierarchy is only helpful if many small incremental steps are used.

It is important in discussing the effects of stimulus intensity to make the distinction between *relative* and *absolute* habituation (Davis & Wagner, 1968). Relative habituation refers to a situation in which habituation is produced and tested with the same stimulus. Absolute habituation refers to a situation in which habituation to one stimulus is tested with another stimulus. The distinction is especially important if the test stimulus is more intense than that used for habituation training. The conditions that are most favorable for absolute and relative ha-

bituation are not necessarily the same. In particular, Davis and Wagner (1968) showed that high-intensity stimuli resulted in more absolute but not in more relative habituation at subsequent testing. Thus, an incremental hierarchy in desensitization might facilitate initial response decrement to the stimuli used in treatment without increasing the amount of response decrement to a separate set of test stimuli. The clinical objective of desensitization is to reduce responsiveness to stimuli of varying intensities that occur in the natural environment and not just to reduce responsiveness to the stimuli used in desensitization training. The potential advantage of habituation to high-intensity stimuli (i.e., flooding) is that it may produce more response decrement when assessed by these "absolute" standards. This assumes, of course, that the sensitization produced by flooding can be successfully managed.

Dual-process habituation theory is certainly better able than maximal habituation theory to explain that both desensitization and flooding are effective anxiety-reduction procedures. It is a serious paradox for maximal habituation theory that a treatment that uses conditions (prolonged exposure to high-intensity stimuli) resulting in high levels of arousal should achieve response decrement at all. The explanation, in terms of dual-process theory, is that whereas desensitization minimizes sensitization, flooding elicits it but also provides long enough exposures for it to decay again. Long sessions are important in getting the best results from flooding (e.g., Stern & Marks, 1973). The repeated growth and decay of sensitization should reduce the extent to which sensitization occurs in the future. One implication of this is that flooding should produce a more generalized reduction in responsiveness than should desensitization, and consistent with this prediction is that Watson and Marks (1971) have shown that flooding to relevant and irrelevant fears is equally effective in the treatment of phobics. On the other hand, it is predicted that systematic desensitization (which, because it uses low-intensity stimuli, is presumably based on habituation rather than on the decay of sensitization) would be markedly more effective if relevant rather than irrelevant fears were used.

Stimulus Lengths

Desensitization usually employs short (e.g., 10 sec) presentations of imaginal stimuli, and normally presentations are terminated sooner if anxiety is reported. Dual-process theory sees the role of short stimulus presentations as also preventing sensitization. They would be especially helpful in doing this if other conditions (i.e., relaxation and low-intensity stimuli) were such that they minimized sensitization. If relaxation and low-intensity stimuli were not used, short presentations of stimuli would probably be able to do little to prevent sensitization from developing, and longer presentations, which allow more time for inferred habituation to take place, would result in a greater degree of response decrement.

There are two experiments that have found such an interaction effect between stimulus lengths and relaxation. Proctor (1969) found that when relaxation was used, desensitization with 5-sec exposures to slides produced more change in subjective anxiety during a subsequent avoidance test than did 20-sec exposures. The reverse obtained if relaxation was omitted. Sue (1975) reported a similar interaction in comparing 5-sec and 30-sec stimulus lengths. In desensitization without relaxation, longer stimulus exposures produced more change on a behavioral avoidance test and on the Fear Survey Schedule (Geer, 1965), but had no significant effect when relaxation was not used. Watts (1971) reported a similar interaction between stimulus intensity and stimulus length. Following a suggestion made by Koepke and Pribram (1966) in their attempt at resolving some apparently conflicting findings in the habituation literature, Watts predicted and found that relatively low-intensity desensitization items habituated to zero anxiety more rapidly with short (5 sec) than with long (30 sec) presentations but that the reverse obtained for higher intensity items.

The advantage of longer presentations is best attributed to the allowance of more time

for habituation to take place rather than to the decay of sensitization. The time scale (30 sec) is probably too short for the decay of sensitization. But in any case, the advantage of longer stimulus presentations is known to be a relatively long-term one, whereas sensitization is relatively transitory in its effects.

Watts (1971) provided evidence for the long-term value of longer stimulus presentation in desensitization. He found that even when reduction to zero anxiety was achieved more rapidly with short presentations, more long-term desensitization was achieved with longer presentations. In the short term the combination of short presentations of low-intensity stimuli and relaxation can apparently prevent the development of sensitization and so appear to facilitate response decrement, but little long-term advantage results from this. Where relaxation or low-intensity stimuli are not used, short presentations are apparently not sufficient to prevent the accumulation of sensitization, and there is not even any short-term advantage in using short stimulus presentations. In this case there is both an immediate and a long-term advantage in using longer stimulus presentations.

Watts (1974) considered in more detail the mechanism by which longer stimulus presentations result in more long-term habituation. He suggested that the amount of long-term response decrement depends on the extent to which the subject forms a clear model of the stimulus (c.f. Sokolov, 1963). In support of this hypothesis, Watts was able to show that describing desensitization items each time they were presented resulted in more long-term anxiety reduction, though it did not affect the rate of response decrement.

It may well be that some of the confusion in the literature about whether relaxation facilitates desensitization could be resolved by taking lengths of stimulus presentation into account. Crowder and Thornton (1970) have drawn attention to the fact that studies such as their own that failed to show that relaxation facilitates desensitization tended to use relatively long presentations. Similarly, it is predicted that the facilitatory effects of a graded stimulus hierarchy would be easier to demonstrate if short stimulus presentations were used.

The interaction effects that have been found between stimulus length and relaxation and between stimulus length and stimulus intensity prove a problem for most theories of desensitization. There have so far been no suggestions as to how they could be predicted from reciprocal inhibition theory or maximal habituation theory. Equally, cognitive theories of desensitization (Kazdin & Wilcoxon, 1976) would have no basis for predicting these effects. They thus provide important empirical support for the dual-process model of desensitization, with which they are in accord.

Interstimulus Interval Length

Another example of the differential effects of procedural variables on short-term and long-term change concerns interstimulus intervals. Though short intervals usually facilitate initial response habituation, they do not increase the amount of long-term habituation (Askew, 1970; Davis, 1970). This facilitatory effect of short-term intervals can be attributed to refractory-period effects. Watts (1973) found that in desensitization also, interstimulus interval lengths have a short-term but not a long-term effect. However, the short-term effect is different from that found in auditory habituation. Longer intervals resulted in faster initial response decrement to relatively high-intensity desensitization items, though they had no effect with low-intensity items. Presumably the longer intervals prevented the accumulation of the sensitization that can occur with high-intensity stimuli, but this preventative effect would not be expected to have any long-term benefit.

Long-Term Anxiety Reduction

One of the central weaknesses of the maximal habituation model, as developed by Lader and Mathews (1968), is its failure to take account of the long-term effects of procedural variables. In particular, as has been argued, Lader and Mathews were probably

incorrect to assume that aspects of the desensitization procedure, such as relaxation and an incremental stimulus hierarchy, that appear to increase the initial rate of anxiety decrement in the short term are also of long-term benefit. In addition, short stimulus lengths and short interstimulus intervals can facilitate anxiety reduction in the short term, but can be of no long-term benefit. In the context of the dual-process theory elaborated here, it has been suggested that variables that facilitate short-term but not long-term decrement operate on sensitization rather than on habituation. But whether or not this is correct, it is now clear that theories of desensitization that do not give explicit consideration to both immediate and long-term effects cannot be adequate. There is a need for a great deal more research on the delayed effects of desensitization sessions. The few investigations published so far (e.g., Agras, 1965; Rachman, 1966) leave many questions unanswered. It is also necessary to become more precise about what is meant by *long-term* effects. Testing at delays of 1 hour, 24 hours, and 1 week may produce quite different results, though it would be impossible to tease out such differences from the currently available research. In the meantime, the dual-process theory developed here has the unique distinction of making specific predictions about immediate and long-term effects.

Conclusion

It is probably too soon to make a final judgment on the adequacy of the habituation model of desensitization, though it can at least be claimed that it is a viable alternative to the reciprocal inhibition theory. Moreover, it has served the useful function of generating fresh problems and hypotheses for investigation. In particular, it has tended to generate more detailed research on the pattern of anxiety reduction than have other theories. In this way it has resulted in some significant advances in our understanding of the processes that operate in systematic desensitization.

Some data have already accumulated (e.g., the interaction effects between stimulus length and relaxation/stimulus intensity) that can be predicted from the dual-process theory, but that appear to pose problems for any other current theory. The need for the future is to make the dual-process theory increasingly precise so that specific predictions from the theory can be tested and, if necessary, refuted. This article has tried to make a contribution to this theoretical task.

The "File Drawer Problem" and Tolerance for Null Results

Robert Rosenthal
Harvard University

For any given research area, one cannot tell how many studies have been conducted but never reported. The extreme view of the "file drawer problem" is that journals are filled with the 5% of the studies that show Type I errors, while the file drawers are filled with the 95% of the studies that show nonsignificant results. Quantitative procedures for computing the tolerance for filed and future null results are reported and illustrated, and the implications are discussed.

Both behavioral researchers and statisticians have long suspected that the studies published in the behavioral sciences are a biased sample of the studies that are actually carried out (Bakan, 1967; McNemar, 1960; Smart, 1964; Sterling, 1959). The extreme view of this problem, the "file drawer problem," is that the journals are filled with the 5% of the studies that show Type I errors, while the file drawers back at the lab are filled with the 95% of the studies that show nonsignificant (e.g., $p > .05$) results.

In the past there was very little one could do to assess the net effect of studies, tucked away in file drawers, that did not make the magic .05 level (Rosenthal & Gaito, 1963, 1964). Now, however, although no definitive solution to the problem is available, one can establish reasonable boundaries on the problem and estimate the degree of damage to any research conclusion that could be done by the file drawer problem.

This advance in our ability to cope with the file drawer is an outgrowth of the increasing interest of behavioral scientists in summarizing bodies of research literature systematically and quantitatively, both with respect to significance levels (Rosenthal, 1969, 1976, 1978) and with respect to effect-size estimation (Hall, 1978; Rosenthal, 1969, 1976; Rosenthal & Rosnow, 1975; Smith & Glass, 1977; Glass, Note 1). One hopes that this interest in summarizing entire research domains will lead to an improvement in bookkeeping so that eventually all results will be recorded both with an estimate of effect size (e.g., r or d; Cohen, 1977) and with the level of significance obtained, or more practically, with the standard normal deviate (Z) that corresponds to the obtained p (Rosenthal, 1978).[1] Future appraisals of research domains of the type found in *Psychological Bulletin* should give estimates of overall effect sizes and significance levels; these estimates of overall significance can provide a basis for coping with the file drawer problem.

Tolerance for Future Null Results

Given any systematic quantitative review of the literature bearing on a particular hy-

Preparation of this article was supported in part by the National Science Foundation.

I would like to thank Judith A. Hall and Donald B. Rubin for their valuable improvements of an earlier version of this article.

Requests for reprints should be sent to Robert Rosenthal, Department of Psychology and Social Relations, Harvard University, 33 Kirkland Street, Cambridge, Massachusetts 02138.

[1] Standard normal deviates (Z) can be found by various methods, of which the following three are most often useful: (*a*) Obtain the exact p associated with the test statistic (e.g., t, F, or χ^2) and find the Z associated with that p in tables of the normal distribution; (*b*) if the effect size r or phi is given or can be computed, Z can be estimated by $r(N)^{\frac{1}{2}}$; (c) if the effect size d is given or can be computed, Z can be estimated by $[d^2/(d^2+4)]^{\frac{1}{2}}(N)^{\frac{1}{2}}$.

pothesis, for example, that psychotherapy is effective (Glass, Note 1), that women are more sensitive than men to nonverbal cues (Hall, 1978), or that one person's expectation for another person's behavior can come to serve as self-fulfilling prophecy (Rosenthal, 1969, 1976), it is easy to calculate an overall probability, based on all the independent studies available to the reviewer, that the effect in question is "real," that is, not a Type I error (Rosenthal, 1978). The fundamental idea in coping with the file drawer problem is simply to calculate the number of studies averaging null results that must be in the file drawers before the overall probability of a Type I error is brought to any desired level of significance, say, $p = .05$. This number of filed studies, or the tolerance for future null results, is then evaluated for whether such a tolerance level is small enough to threaten the overall conclusion drawn by the reviewer. If the overall level of significance of the research review will be brought down to the level of *just significant* by the addition of just a few more null results, the finding is not resistant to the file drawer threat.

Computation

Perhaps the simplest, most useful way of computing the overall p of a set of research studies is the method of adding Zs (Cochran, 1954; Mosteller & Bush, 1954; Rosenthal, 1978). This method requires only that one add the standard normal deviates of Zs associated with the ps obtained and divide by the square root of the number of studies being combined. The result is itself a Z that can be entered in a table to find the associated overall p:

$$Z_c = k\bar{Z}_k/\sqrt{k} = \sqrt{k}\bar{Z}_k, \qquad (1)$$

where Z_c is the new combined Z, k is the number of studies combined, and $\bar{Z}_k$ is the mean Z obtained for the k studies.

To find the number (X) of new, filed, or unretrieved studies averaging null results required to bring the new overall p to any desired level, say, just significant at $p = .05$ ($Z = 1.645$), one simply writes:

$$1.645 = k\bar{Z}_k/\sqrt{k + X}. \qquad (2)$$

Rearrangement shows, then, that

$$X = (k/2.706)[k(\bar{Z}_k)^2 - 2.706]. \qquad (3)$$

An alternative formula that may be more convenient when the sum of the Zs (ΣZ) is given rather than the mean Z is as follows: $X = [(\Sigma Z)^2 / 2.706] - k$. One method based on counting rather than adding Zs may be easier to compute and can be employed when exact p levels are not available; but it is probably less powerful. If X is the number of new studies required to bring the overall p to .50 (not to .05), s is the number of summarized studies significant at $p < .05$, and n is the number of summarized studies not significant at .05, then $X = 19s - n$. Another conservative alternative when exact p levels are not available is to set $Z = .00$ for any nonsignificant result and to set $Z = 1.645$ for any result significant at $p \leq .05$.

Equations 1, 2, and 3 all assume that each of the k studies is independent of all other $k - 1$ studies, at least in the sense of employing different sampling units. There are other senses of independence, however; for example, one can think of two or more studies conducted in a given laboratory as less independent than two or more studies conducted in different laboratories. Such nonindependence can be assessed by intraclass correlations. Whether nonindependence of this type serves to increase Type I or Type II errors appears to depend in part on the relative magnitude of the Zs obtained from the studies that are correlated or too similar. If the correlated Zs are, on the average, as high (or higher) as the grand mean Z corrected for nonindependence, the combined Z one computes by treating all studies as independent will be too large. If the correlated Zs are, on the average, clearly low relative to the grand mean Z corrected for nonindependence, the combined Z one computes by treating all studies as independent will tend to be too small.

Illustration

In 1969, 94 experiments examining the effects of interpersonal self-fulfilling prophecies were summarized (Rosenthal, 1969). The mean Z of these studies was 1.014, k was 94, and Z_c for the studies combined was $9.83 = 94(1.014)/(94)^{\frac{1}{2}}$.

How many new, filed, or unretrieved studies (X) would be required to bring this very large Z down to a barely significant level ($Z = 1.645$)? By Equation 3,

$$X = (94/2.706)\ [94(1.014)^2 - 2.706] = 3{,}263.$$

One finds that 3,263 studies averaging null results ($\bar{Z} = .00$) must be crammed into file drawers before one would conclude that the overall results were due to sampling bias in the studies summarized by the reviewer. In a more recent summary of the same area of research (Rosenthal, 1976), the mean Z of 311 studies was 1.180, k was 311, and X was 49,457! Thus, nearly 50,000 unreported studies averaging a null result would have to exist somewhere before the overall results could reasonably be ascribed to sampling bias.

Discussion

There is both a sobering and a cheering lesson to be learned from careful study of Equation 3. The sobering lesson is that small numbers of studies that are not very significant, even when their combined p is significant, may well be misleading in that only a few studies filed away could change the combined significant result to a nonsignificant one. Thus, 15 studies averaging a Z of .50 have a combined p of .026; but if there were only 6 studies tucked away showing a mean Z of .00, the tolerance level for null results would be exceeded, and the significant result would become nonsignificant (i.e., $p > .05$). Or if there were 2 studies averaging a Z of 2.00, the combined p would be about .002; but uncovering 4 new studies averaging a Z of .00 would bring p into the *not significant* region.

The cheering lesson is that when the number of studies available grows large or the mean directional Z grows large, the file drawer hypothesis as a plausible rival hypothesis can be safely ruled out. If 300 studies are found to average a Z of $+1.00$, it would take 32,960 studies to bring the new combined p to a nonsignificant level; that many file drawers full is simply too improbable.

At the present time no firm guidelines can be given as to what constitutes an unlikely number of unretrieved or unpublished studies. For some areas of research 100 or even 500 unpublished and unretrieved studies may be a plausible state of affairs, whereas for others even 10 or 20 seems unlikely. Probably any rough and ready guide should be based partly on k so that as more studies are known it becomes more plausible that other studies in that area may be in those file drawers. Perhaps one could regard as resistant to the file drawer problem any combined results for which the tolerance level (X) reaches $5k + 10$. This seems a conservative but reasonable tolerance level; the $5k$ portion suggests that it is unlikely that the file drawers have more than five times as many studies as the reviewer, and the 10 sets the minimum number of studies that could be filed away at 15 (when $k = 1$).

It appears that more and more reviewers of research literature are estimating average effect sizes and combined ps of the studies they summarize. It would be very helpful to readers if for each combined p they presented, reviewers also gave the tolerance for future null results associated with their overall significance level.

Psychological Bulletin

(Continued on inside back cover)

BLISHED BIMONTHLY BY THE AMERICAN PSYCHOLOGICAL ASSOCIATION
ISSN 0033-2909

The *Psychological Bulletin* publishes evaluative reviews and interpretations of substantive and methodological issues in the psychological research literature. The Journal reports original research only when it illustrates some methodological problem or issue. Discussions of methodological issues should be aimed at the solution of some particular research problem on psychology, but should be of sufficient breadth to interest a wide readership among psychologists; articles of a more specialized nature can be directed to the various statistical, psychometric, and methodological journals. The *Bulletin* does not publish original theoretical articles; these should be submitted to the *Psychological Review*.

Abstracts: All articles must be preceded by an abstract of 100–175 words. Detailed instructions for preparation of abstracts appear in the *Publication Manual of the American Psychological Association* (2nd ed.), or they may be obtained from the Editor or from APA Central Office.

Blind review: Because reviewers have agreed to participate in a blind reviewing system, authors submitting manuscripts are requested to include with each copy of the manuscript a cover sheet, which shows the title of the manuscript, the name of the author or authors, the author's institutional affiliation, and the date the manuscript is submitted. The first page of the manuscript should omit the author's name and affiliation but should include the title of the manuscript and the date it is submitted. Footnotes containing information pertaining to the author's identity or affiliation should be on separate pages. Every effort should be made to see that the manuscript itself contains no clues to the author's identity.

Manuscripts: Submit manuscripts in triplicate to the Editor, R. J. Herrnstein, *Psychological Bulletin,* Harvard University, 33 Kirkland Street, Cambridge, Massachusetts 02138, according to instructions provided below.

Instructions to Authors: Authors should follow the directions given in the *Publication Manual of the American Psychological Association* (2nd ed.). Instructions on tables, figures, references, metrics, and typing (all copy must be double-spaced) appear in the Manual. Authors are requested to refer to the "Guidelines for Nonsexist Language in APA Journals" (Publication Manual Change Sheet 2, *American Psychologist,* June 1977, pp. 487–494) before submitting manuscripts to this journal. All manuscripts should be submitted in triplicate and all copies should be clear, readable, and on paper of good quality. Dittoed copies are not acceptable and will not be considered. Authors are cautioned to carefully check the typing of the final copy and to retain a copy of the manuscript to guard against loss in the mail.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $40 domestic, $42 foreign, $7 single issue. APA member rate: $15. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Dept., APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published bimonthly (beginning in January) in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Arlington, Va., and at additional mailing offices.

Paradoxical Tranquilizing and Emotion-Reducing Effects of Nicotine

David G. Gilbert
Florida State University

Investigations of the effects of nicotine on emotion and on indices of central and autonomic nervous system arousal are reviewed. Mechanisms that may account for the paradoxical finding that nicotine increases autonomic nervous system end-organ arousal yet has frequently been reported to reduce self-report and behavioral indices of emotion are evaluated. A number of mechanisms have been proposed, but none are backed by a convincing network of supportive data. The literature suggests that the mechanism(s) by which nicotine reduces indices of emotion is influenced by a wide variety of variables, including behavioral activity level, central nervous system arousal level, type of emotion, time since the administration of the drug, and the rate and dose of its administration. There is the need to demonstrate a paradigm that reliably causes nicotine-induced reductions of emotion. Once reliability has been established, further studies can vary the paradigm's potentially influential variables.

One of the most paradoxical and intriguing facts in the field of emotions is that smoking and nicotine cause significant increases in physiological arousal, especially of autonomic end organs, yet frequently reduce behavioral and self-report measures of emotion and cause people to report feelings of increased tranquility (Frith, 1971; Ikard, Green & Horn, 1969; Ikard & Tompkins, 1973). This paradox is underscored by the fact that a number of major popular theories of emotion (Lange & James, 1922; Mandler, 1975; Schachter & Singer, 1962) view increased autonomic arousal as an essential component of emotional processes. Possibly because of the relevance of this paradox to current theories of emotion and smoking, there have been an increasing number of studies that pertain to the resolution of these apparently contradictory findings.

Although some investigators have summarized various parts of the literature relevant to nicotine's emotion-decreasing and physiological - arousal - increasing properties, there has been no extensive review of studies selected for their relevance to the clarification of the physiological and psychological mechanisms that underlie these apparently contradictory effects. This review represents

---

An earlier version of this article was submitted to the Department of Psychology, Florida State University in partial fulfillment of the requirements for the PhD.

The author wishes to express his appreciation to Richard Hagen, Stephen West, Jack May, James Smith, and James Orcutt for their helpful comments.

Requests for reprints should be sent to David Gilbert, who is now at the North Central Florida Community Mental Health Center, 3615 S.W. 13th Street, Gainesville, Florida 32608.

an attempt to come closer to a determination of what these underlying mechanisms might be. First, studies demonstrating the paradox are reviewed. Then, mechanisms that have been proposed to explain the paradox are reviewed and evaluated in terms of their supporting evidence.

Paradox: Increased Autonomic Nervous System Activation With Decreased Emotion

Physiological Effects of Nicotine

The paradox exists only to the degree that nicotine produces simultaneous increases in physiological arousal and decreases in emotional experience or behavior. An examination of the effects of nicotine on physiological arousal and emotion is complicated by the lack of single definitive indices of either *emotion* or *physiological arousal,* concepts that are not homogeneous entities but instead are categories or constructs that represent a wide variety of different processes. Therefore, a variety of different indices of each of these categories are reviewed.

Effects on autonomic nervous system end organs. The smoking of one or two cigarettes or the administration of an equivalent amount of nicotine by other means typically causes significant sympathomimetic symptoms, the most notable of which include an increase in resting heart rate of from 5 to 40 beats per minute (Domino, 1973; Hill & Wynder, 1974; Roth, McDonald, & Sheard, 1945), increased blood pressure (5 to 20 mm of Hg), increased serum levels of epinephrine and adrenalcortical compounds (Herxheimer, Griffiths, Hamilton, & Wakefield, 1967; Hill & Wynder, 1974; Jarvik, 1970), and significant vasoconstriction (Herxheimer et al., 1967; Simon & Iglauer, 1967).

Almost all of the studies of the effects of nicotine on autonomic nervous system (ANS) arousal have maintained subjects in quiescent, nonemotional states prior to and after the administration of nicotine. Hence, there is some question about the extrapolation of these studies to subjects in active states, and evidence is quite meager in relation to this question. Two studies do support the notion that quiescent-state research is broadly applicable. These two studies found that high-nicotine cigarettes produced significantly greater increases in heart rate than low-nicotine cigarettes in moderately arousing emotional settings (Gilbert, 1978; Nesbitt, 1973). However, a study by Erwin (1971) found that heart rate did not increase after the onset of smoking in subjects who moved about, performing their daily routines.

Mechanisms by which nicotine induces these sympathetic symptoms have been reported to include direct effects of nicotine on the particular end organs and indirect effects brought about by nicotine-induced increases of serum epinephrine, which, in turn, stimulates these end organs (Jarvik, 1970; Meyers, Jawetz, & Goldfien, 1974).

Effects on central nervous system activity and structures. Contrary to the hypothesis that tobacco and nicotine produce central nervous system (CNS) tranquilizing effects, studies have typically shown that smoking-sized doses of nicotine (.005 to .1 mg per kg of body weight) produce electroencephalogram (EEG) activity characteristic of CNS arousal (alpha desynchronization, increased dominant alpha frequency, and reduction in total energy and variability of cortical EEG activity). The EEG arousal occurs immediately after the intravenous administration of nicotine and by the time the individual completes smoking a tobacco cigarette. Several studies using subhuman mammals have reported this initial phase of EEG arousal to be followed by a phase of EEG tranquilization that occurs about 5–15 minutes after the intravenous administration of the drug and lasts up to 30 minutes (Bhattacharya & Goldstein, 1970; Domino, 1967; Goldstein, Beck, & Mundschenk, 1967). However, no such secondary phase of EEG tranquilization has been shown to occur in humans. Philips (1971) reported that the smoking of a single cigarette resulted in a significant increase in EEG arousal (mean alpha power reduction) for up to 20 minutes. Similarly, Knott and Venables (1977) found that smoking two cigarettes resulted in EEG arousal (increased dominant alpha frequency) for the duration of their recording period (15 minutes). Nu-

merous other studies have also shown that smoking and intravenous and subcutaneous administration of nicotine induce EEG arousal in humans (Bickford, 1960; Hauser, Schwartz, Roth, & Bickford, 1958; Murphree, Pfeiffer, & Price, 1967; Wechsler, 1958) and in animals (Domino, 1973). However, one series of studies (Armitage, Hall, & Morrison, 1968) showed that the effects of small amounts of nicotine depended critically on dose and rate of administration when EEG and acetylcholine measures of cortical arousal were used in rats and cats. Furthermore, at some given doses and rates, it appeared that cortical arousal could be either increased or decreased, the effect varying from cat to cat.

On the other side of the coin, studies of smoking abstinence effects have consistently shown EEG sedation or depression effects following smoking deprivation (Itil, Ulett, Hsu, Klingenberg, & Ulett, 1971; Knott & Venables, 1977; Murphree & Schultz, 1968; Ulett & Itil, 1969). Deprivation also causes restlessness and dysphoria (Shiffman & Jarvik, 1976; Ulett & Itil, 1969). This simultaneous occurrence of EEG tranquilization and subjective dysphoria calls into question the validity of classical EEG measures as indices of emotional arousal. Furthermore, the occurrence of restlessness concurrently with EEG tranquilization calls into question the use of these EEG measures as indices of general arousal or activation level.

The EEG-activating effects of smoking have been interpreted in a number of studies (Bickford, 1960; Hauser et al., 1958; Wechsler, 1958) as resulting from the behavioral act of smoking rather than from the physiological effect of nicotine or other pharmacological substances present in tobacco. Studies systematically varying the nicotine content of the cigarette smoked and studies using intravenous administration of nicotine in humans are urgently needed. However, the animal studies mentioned above, which used smoking-sized intravenous doses of nicotine, have shown that nicotine induces classical EEG signs of arousal, a finding that strongly supports the view that nicotine is at least partially responsible for the EEG-arousing properties of smoking.

Less traditional, but possibly more sophisticated, measures of CNS arousal present a more complex picture of the effects of nicotine. Brown (1967) reported that intravenous nicotine produced a state of mixed arousal and sedation in cats. After nicotine administration, these cats demonstrated a behavioral state of drowsiness combined with a substained potential for alertness. Nicotine also produced an unusual partitioning of EEG activity. Consistent with arousal, there was a net decrease in energy content when all EEG frequencies were considered, but there was a sedative effect (increased energy content) among lower frequency ranges. Nicotine also led to a persistence of hippocampal theta frequency, which is characteristic of orienting responses. Finally, nicotine resulted in evoked responses in the hippocampus similar to those obtained during sleep. Vazquez and Toman (1967) also found that nicotine produced mixed and hard-to-explain effects on directly evoked brain potentials. In rabbits, they found that nicotine caused transient depression of the most prominent fast component but enhancement of the most prominent slow, negative component.

In studies with humans, the effects of cigarette smoking on cortical, average visually evoked potential and contingent negative variation indices of cortical arousal suggest that nicotine influences cortical processes in a complex manner that can be either arousing or sedating, depending on the nature of the stimulus and the personality characteristics of the individual. Smoking has produced an arousing (increased response amplitude) effect on average visually evoked potentials elicited by low-intensity stimuli and a sedative effect on potentials elicited by high-intensity stimuli (R. A. Hall, Rappaport, Hopkins, & Griffin, 1973). On the other hand, Ashton, Millman, Telford, and Thompson (1974) reported that smoking produced cortical arousal (increased contingent negative variation magnitude) in extraverts, but had the opposite effect (sedation) in introverts. This finding of the effects' dependence on personality is consistent with the findings of Brown (1967) and Armitage et al. (1968), which showed that

the effects of nicotine in cats and rats can either arouse or depress EEG, cortical evoked potentials, and cortical acetylcholine production, depending on the characteristic behavior of the individual animal.

In conclusion, nicotine typically causes increases in the more traditional and gross measures of general CNS arousal when the prenicotine arousal state of the organism is low. However, more detailed and sophisticated measures of arousal show that the effects of nicotine on CNS activity are multiple and depend on a variety of parameters. The picture is further complicated by reports of the onset of cortical sedation some 5 or 10 minutes after the onset of arousal in cats and rabbits, but not in humans, and by findings of differential effects of smoking and nicotine with different doses and behavioral predispositions. These conclusions indicate that future research should control for and systematically investigate the effects of these variables. Also, the findings of mixed arousal and sedation and of insignificant correlations between measures of CNS arousal indicate a need for simultaneous measurement of a variety of indices in different parts of the brain. Furthermore, this discordance of measures suggests that the concept of cortical or CNS arousal is inadequate to handle the data at hand. The inadequacy of the arousal construct is also attested to by the findings showing that smoking deprivation causes the simultaneous occurrence of EEG tranquilization and subjective restlessness–dysphoria.

These inadequacies and the fact that the effects of nicotine on the CNS are highly complex and dependent on numerous parameters suggest that a multiple interacting systems model is preferable to a unidimensional arousal model when one studies the effects of nicotine on brain activity and emotions. Such a systems approach suggests that consideration should be given to whether we are asking the right questions of the right parts of the CNS.

This systems approach also stresses the importance of the mutual influence of various bodily systems on each other. In this line, it should be noted that alterations in CNS activity brought about by nicotine have usually implicitly been assumed to be the direct result of nicotine's effects on CNS mechanisms and structures. This assumption may, however, be in error, since the primary sites of nicotine's action may result from at least two other sources. First, Bickford (1960) has reviewed a number of changes in peripheral bodily states (e.g., respiration rate, blood carbon dioxide and sugar levels, and drug-induced alterations of peripheral organ activity) that have been shown to influence EEG activity.

The important role that peripheral bodily and psychological states have in influencing EEG activity makes it clear that a major problem with studies of the effects of nicotine on CNS arousal is that nearly all the studies have maintained their subjects in a low-arousal, quiescent baseline state before the administration of nicotine. The absence of studies whose subjects were in emotional or other high-arousal conditions before the administration of the drug makes the relevance of these studies to the suggested tranquilizing properties of nicotine very questionable. Future studies that systematically vary prenicotine arousal level are urgently needed. A related difficulty is the problem of generalization from restricted laboratory states of low stimulus input and low activity level to more natural and emotional states.

Effects of nicotine on skeletal muscle activity. A number of findings are consistent with the possibility that some of nicotine's tranquilizing effects may result from the tendency of nicotine to reduce muscular tension and responses to emotional stimuli. A rapid, short-lived reduction in muscular tension in spastic patients was observed after each subject smoked a single cigarette (Webster, 1964). Also, a depression of the patellar tendon reflex (knee jerk) and associated musculature has been demonstrated in humans (Domino, 1973) and other mammals (see review by Silvette, Hoff, Larson, & Haag, 1962) following the administration of small amounts of nicotine. Furthermore, diminution of aversive-stimulation-induced jaw contractions and associated muscle potentials has been reported in human and

monkey subjects following smoking and the intravenous and oral administration of nicotine (Hutchinson & Emley, 1973). It seems reasonable to assume that reductions of muscular activity in response to emotional stimuli are subjectively experienced as emotion reducing or tension relieving; thus, these effects of nicotine on muscular activity are consistent with reports of nicotine's tranquilizing properties. Somewhat inconsistent with this hypothesis, the flexor reflex has been shown to be relatively unaffected by as well as enhanced by nicotine (Silvette et al., 1962). Nonetheless, overall, the evidence suggests that potentially significant reductions of various muscular activity or responses result when nicotine is administered.

Nicotine may reduce muscular activity and tension by causing CNS emotional centers to reduce emotional motoric output, or its action may be more peripheral, such as in the spinal cord, the neuromuscular junction, or the muscles themselves. Domino (1973) has cited evidence that suggests that the mechanisms of the reduction are complex and involve both central and peripheral components. Obviously, there is a need for further studies of the effects of nicotine on stress and emotion-induced muscular activity.

Summary. The physiological effects of smoking are essentially identical to those produced by the administration of equivalent doses of nicotine by other means. The predominant effect of nicotine on peripheral bodily structures is that of activation of end organs of the ANS in a sympathomimetic manner. It is true that the effects of nicotine on skeletal muscle action and on CNS activities are more complex and less well understood and established. However, the establishment of the paradox only requires that nicotine be shown to increase ANS arousal while simultaneously decreasing indices of emotion. The demonstration of the latter of these two requirements is now addressed.

Tranquilizing and Emotion-Reducing Effects of Nicotine

Self-reports. A majority of smokers report that they smoke to reduce negative affect or to achieve pleasurable relaxation (Ikard et al., 1969; Ikard & Tompkins, 1973). In a national sample of over 2,000 smokers, Ikard et al. found that 80% scored high on the factor of items indicating that they always or usually smoked for pleasurable relaxation. However, approximately one quarter of this large sample also reported smoking at times for the purpose of stimulation. Frith (1971) asked 59 men and 39 women to imagine themselves in 12 high-arousal situations and 10 low-arousal situations and to indicate on a 7-point scale what their desire for a cigarette would be. Smokers reporting smoking a large number of cigarettes per day indicated a high desire to smoke in both the high- and low-arousal situations. Less heavy smokers, however, could be broken into two groups, those who reported a great desire to smoke in low-arousal situations and those who reported a great desire to smoke in high-arousal situations. More men indicated a strong desire to smoke in the low-arousal circumstances, whereas more women reported a strong desire to smoke in the high-arousal situations.

Experimental studies have also shown that smoking and other means of administering nicotine reduce reports of experienced emotion. In the earliest of these studies, Johnston (1942) published a series of observations of the effects of nicotine on smokers and nonsmokers. Nonsmokers given 1.3-mg hypodermic injections of nicotine reported that an unpleasant light-headedness or muzziness appeared about 5 minutes after the injection. Smokers experienced the same sensations, but described them as pleasant. One patient receiving 4.3 mg of nicotine in water orally three times per day stated that it "steadied" her more than did phenobarbital. Heimstra (1973) described a series of better designed and controlled experiments in which groups of smokers were or were not allowed to smoke. If nicotine reduces emotions, withholding nicotine should increase emotions relative to not withholding nicotine. Smoking reduced the reported amount of mood change that occurred from before to after a series of tasks (6 hours of driving stimulation and 3 hours of pursuit rotary tracking, target detection, and reaction time tasks) and from

before to after a stressful movie. Smoking consistently reduced the mood factors of aggression and anxiety, as measured by the Mood Adjective Check List (Nowlis, 1965).

In a related series of studies, Frankenhaeuser and Myrsten and their associates have shown that in smoking-deprived (up to 15 or more hours) subjects, mental efficiency and subjective well-being are increased in a smoking situation as compared to a nonsmoking situation (Frankenhaeuser, Myrsten, & Post, 1970; Frankenhaeuser, Myrsten, Waszak, Neri, & Post, 1968; Myrsten, Post, Frankenhaeuser, & Johansson, 1972). In one of these studies (Myrsten et al., 1972), for example, smoking during reaction time tasks led to decreased self-estimates of irritation and boredom, as compared to the nonsmoking condition.

In an experiment by Ague (1973), subjects suspended smoking for 8 hours, rated their moods, and then smoked one of four cigarettes of varying nicotine content. An hour after smoking subjects again rated their moods. Subjects rated themselves as feeling significantly more pleasant and relaxed an hour after smoking high-nicotine cigarettes than they felt an hour after smoking low- or no-nicotine ones. Nicotine dose level did not result in statistically significant differences on other Mood Adjective Check List factors (Aggression, Anxiety, Surgency, Concentration, Fatigue, Vigor, and Sadness), but there was a nonsignificant tendency for nicotine to reduce anxiety and aggression.

In summary, it can be said that smoking has consistently led, in the published studies to date, to improved mood states in deprived smokers; but the question as to whether this improvement is caused by effects of nicotine or by the oral and manipulative activities involved in smoking has not been addressed by any of the studies other than that of Ague (1973). The probability that oral and manipulative activity is at least partially responsible for the calming effects of smoking seems very high in light of Freeman's (1948) work, which has shown that oral activity reduces anxiety measured by self-report. It is essential, therefore, that future studies control for the variety of smoking-associated behaviors by varying the nicotine content of the cigarettes smoked. The one reported study that did vary the nicotine content of cigarettes smoked (Ague, 1973) found that only two of the nine measured emotions (moods) were reduced or improved, and it is questionable whether these two self-report measures (*pleasantness* and *inner tension*) represented true or complete emotions. Even more desirable would be studies administering nicotine to humans by means other than smoking (e.g., intravenous, oral, or subcutaneous administration). Such means of manipulating nicotine level would control for taste differences among cigarettes of different nicotine contents and could more definitively demonstrate the emotion-reducing properties of the drug.

There is also a need for future studies that present emotional stimuli while varying nicotine level. Since most studies to date have not presented emotion-eliciting stimuli, they have in fact dealt with moods rather than with emotions. Finally, the question of whether nicotine also produces tranquilization in nonsmokers needs investigation.

Behavioral measures. Only two studies have investigated the effects of nicotine on behavioral measures of emotion in humans. The first of these investigations is that of Nesbitt (1973), who found that habitual smokers behaved less emotionally (were willing to endure stronger intensities of electrical shock) when smoking than when simulating smoking. He also found that smokers of a high-nicotine cigarette behaved less emotionally than smokers of a low-nicotine cigarette. He interpreted this study as suggesting that nicotine can reduce emotional behavior; however, the results are open to other plausible interpretations. First, Nesbitt noted that an alternative explanation is the possibility that smokers of the high-nicotine cigarette were satisfied with the cigarette they were allowed to smoke, whereas smokers in the no-cigarette condition were initially told they would be allowed to smoke but later were informed that they would not be allowed to smoke after all, so that the no-cigarette condition may have led to feelings of frustration and anger with an associated decrease in desire to please the ex-

perimenter by enduring the shocks. Similarly, low-nicotine cigarettes generally are considered to be less satisfying than cigarettes of normal nicotine content, and the former, therefore, may have produced feelings of frustration or dissatisfaction similar to the feelings of the no-nicotine subjects, although not as strong. A second alternative interpretation is related to the finding that nicotine increases detection thresholds for electrical shock (Mendenhall, 1925; Wenusch & Schöller, 1936). It may be, therefore, that nicotine decreases the perception of shock and thus accounts for the increased tolerance of shock. Thus, Nesbitt's results are consistent with the hypothesis that nicotine reduces emotional behavior, but they also are in line with alternative explanations.

In the second study, Schechter and Rand (1974) found that habitual smokers deprived of smoking were 37% more aggressive on a Buss (1961) aggression machine task than were subjects who were allowed to smoke. Unfortunately, the deprived smokers did not have the opportunity to engage in the same oral and manipulative behaviors as did smokers. As a result of this confound, no conclusion as to the role of nicotine can be reached.

In summary, too few studies have been reported and too many methodological problems are evident in the studies that are available to permit a definite statement about the role of nicotine in altering emotional behavior in humans. It can, however, be said that the studies reported to date suggest that nicotine may be able to reduce anxiety and aggression in habitual smokers, as determined by behavioral measures.

Emotion in animals. The leap from the discussion of emotions in man to emotions in subhuman animals is, of course, a questionable proposition, since there is no assurance that the "anger" or "anxiety" that a rat, for example, experiences corresponds in a significant manner to their counterparts in humans. Nonetheless, the effects of nicotine on behavioral measures of emotion in subhuman species have received increased attention during the last decade, and some strong trends appear to be developing in this area. First, animal studies have consistently shown that smoking-dose levels of nicotine reduce a variety of measures of aggression. For example, Silverman (1971) found a consistent reduction of aggression in both albino and hooded rats following small subcutaneous doses of nicotine. Sexual, investigatory, and submissive behaviors were also reduced very slightly, but general activity level was not significantly influenced. Consistent with these findings, Hutchinson and Emley (1973) reviewed a series of experiments that they and their co-workers have completed in recent years showing that the acute oral administration of small doses of nicotine (.04–.80 mg/kg) and the chronic oral administration of even smaller doses (as small as .002 mg/kg) reduced postshock biting in monkeys while simultaneously increasing preshock anticipatory motor behaviors. These two simultaneous effects were also produced in their studies by two tranquilizers (chlorpromazine and chlordiazepoxide) and have been said to be characteristic of tranquilizer-type compounds (Emley & Hutchinson, 1972). These researchers also found that withholding nicotine after chronic administration caused increases in their measures of aggression. The findings of less well-designed studies by Schechter (1974) and Kostowski (1968) are consistent with this general picture, in that they also showed nicotine-produced decrements of aggression in rats and ants, respectively.

Indices of fear and anxiety in animals have typically been reduced by nicotine, but these effects have been less consistent than the effects of nicotine on aggression. A number of researchers (Bovet, Bovet-Nitti, & Oliverio, 1966; Essman & Essman, 1971; Fleming & Broadhurst, 1975; Hutchinson & Emley, 1973; Morrison & Stephenson, 1972) have reported that nicotine reduces measures of anxiety (immobility, conditioned suppression, exploratory behavior) in a variety of animals. On the other hand, Davis, Kensler, and Dews (1973) and Driscoll and his coworkers (Driscoll, 1976; Driscoll & Bättig, 1970; Driscoll & Bättig, 1974) have reported nicotine-produced increases in indices of anxiety–fear (punishment-induced suppression of operant behavior and avoidance behavior).

Studies of the effects of nicotine on cor-

relates and indices of anxiety–fear in subhuman species are difficult to interpret not only because of apparently contradictory results but also because nicotine has a strong tendency to increase all forms of operant behavior, those motivated by a fear component and those that are not. Consistent with the emotion-reduction hypothesis, Hutchinson and Emley (1973) found what might be considered one of the best correlates of anxiety—conditioned suppression of positively reinforced behavior—to be reduced by low and intermediate doses of nicotine (.1–.4 mg/kg) administered subcutaneously in monkeys and rats. Also consistent with the suggestion that nicotine reduces anxiety are the findings of studies that have shown increased mobility and exploratory behavior in threatening environments, that is, in shock avoidance conditions (Fleming & Broadhurst, 1975; Morrison & Stephenson, 1972). These studies showing a reduction of the suppression of operant behavior, however, cannot be cited as strong support indicative of nicotine-induced reduction of anxiety–fear, since nicotine also increases a wide variety of operant behaviors not related to negative emotions.

The findings that have been interpreted as suggestive of nicotine-induced increases, rather than decreases, of fear and anxiety involve, for the most part, avoidance paradigms. Small and moderate doses (.5–.30 mg/kg) of nicotine, like caffeine and amphetamine, increase bar pressing in avoidance tasks (Balfour & Morrison, 1975; Davis et al., 1973). This increased rate of avoidance behavior is characteristically produced by stimulant drugs and does not nessarily indicate increased fear or anxiety, as evidenced by the fact that nicotine and stimulant drugs also increase operant behavior not related to negative emotions.

Studies testing the effects of nicotine on punishment-induced suppression of positively reinforced behavior in one case (Morrison, 1969) showed that nicotine and amphetamine reduced the punished behavior to below control values (which would be consistent with nicotine's having anxiety-increasing properties), whereas a tranquilizer (chlordiazepoxide) increased responding to nonpunished levels. However, a more recent study (Morrison & Stephenson, 1972) showed that both amphetamine and nicotine slightly increased behavior that had simultaneous rewarding and aversive properties. In this latter case, these two drugs appear to have an antianxiety effect.

In summary, a review of the effects of nicotine on behavioral measures of emotion in subhuman species suggests that the drug reduces a variety of aggressive behaviors, but its effects on other forms of emotional behavior are still open to question. In view of the mixed and hard-to-interpret effects of nicotine on behavioral indices of anxiety–fear, future research should investigate the importance of the variety of variables suggested earlier in this review in determining whether nicotine has stimulant or sedative properties. These variables include individual and strain differences, dose, paradigm type, rate of nicotine administration, intensity of emotion-inducing stimuli, preexperimental arousal level, and type of emotion.

Summary of the emotion-reducing effects of nicotine. The studies reviewed suggest that, at least in some situations, nicotine has emotion-reducing properties in man and animals and that nicotine deprivation in chronic users causes relative increases of emotion. All 12 of the reported studies with humans have been consistent with the hypothesis that nicotine has this effect. Furthermore, nicotine reduced indices of aggression in animals in all 7 studies available for review. And with the exception of avoidance measures, nicotine also has reduced correlates of anxiety–fear in animals (even though these studies are open to alternative explanations).

There is moderately strong evidence for the existence of the paradox: Nicotine significantly increases arousal of essentially all aspects of the ANS, frequently increases indices of CNS arousal, and at the same time frequently results in reduced negative emotional feelings and behavior and in increased feelings of tranquility and pleasure. The question as to whether nicotine has tranquilizing properties in humans who are not chronic users of the drug has not been answered. The studies involving human subjects have a number of methodological flaws,

but are consistent with the animal literature in suggesting that nicotine reduces indices of emotion.

Mechanisms Proposed to Explain the Paradox

It is important to note that the different mechanisms that have been proposed as explanations of nicotine's probable emotion-reducing properties are not necessarily mutually exclusive. Most of the mechanisms deal with only one level of analysis, so that different mechanisms may account for only part of the picture in a manner similar to the "blind men and the elephant" analogy. In addition, it should be kept in mind that since nicotine produces a large number of direct and indirect physiological changes, the different proposed mechanisms concern themselves with the primary sites of nicotine's action, this primary action then leads to immensely complex chains of further action involving hormonal, neural, behavioral, and experiential changes.

Addiction, withdrawal, and related processes cannot be considered adequate explanations of the paradox without specifically noting by what mechanism nicotine decreases emotion while simultaneously increasing arousal. Inconsistent with the view that the paradox is a manifestation of an addictive process, each dose of nicotine produces transient increases of arousal relative to chronic arousal levels (Ague, 1973; Gilbert, 1978). Also, the paradox has been shown to appear in individuals with no prior experience with the drug (Hutchinson & Emley, 1973). However, the opponent-process theory of addictions and emotions (Solomon & Corbit, 1973) is helpful in that from it one can infer that nicotine may reduce emotion by one mechanism after its chronic administration and by another mechanism in individuals without extensive prior use. Furthermore, the opponent-process theory of addictions leads one to speculate that individuals may adapt to the heightened arousal levels brought about by nicotine and that depriving the addict results in a decrease of arousal that may be subjectively experienced as aversive and thus cause the subject to respond with more emotion. Consistent with this hypothesis, Heimstra (1973) has reported data showing that deprived smokers report simultaneous decreases in arousal (increased fatigue) and increases in aggression and anxiety.

This review is limited to the effects of nicotine. Therefore, it does not consider oral, manipulative, attentional, attributional, and other psychological and behavioral factors associated with smoking independent of nicotine, even though these factors may be very important in producing the satisfying effects of smoking.

CNS Mechanisms

Neurophysiological model. Miller (1973) pointed to a finding in his laboratory that showed that chemomicrostimulation-induced activation of muscarinic neurons in certain portions of the cat brain elicited aggression. He suggested that if the effects of muscarinic and nicotinic central cholinergic neural systems are antagonistic like those of alpha and beta adrenergic systems, then nicotine's calming effect would be explained, since nicotine stimulates the nicotinic neural system and this system tends to inhibit the aggression-producing muscarinic system. Consistent with this hypothesis, Silverman (1971) has noted that the behavioral effects of nicotine are similar to those of benactyzine, which antagonizes the muscarinic effects of acetylcholine. However, this study provides only indirect evidence, and the literature does not appear to provide more direct tests of the proposed nicotinic–muscarinic antagonism. Thus, the status of the hypothesis must be considered speculative and in need of systematic study.

This proposed inhibition of muscarinic aggression circuits by nicotine may prove to account for nicotine's ability to reduce certain forms of aggression, but it does not account for the drug's apparent ability to lessen emotions other than aggression. It is not clear whether nicotine reduces different emotions by altering emotion-specific neurophysiological pathways or by influencing a pathway or process common to all emotions. If the former were true, the effects of nicotine on different emotions would be expected to

vary more widely from emotion to emotion than if the latter were true.

A review of the literature (Avis, 1974) makes it abundantly evident that the role of neurotransmitter systems in the elicitation and inhibition of emotion is extremely complex. This regulation of emotions is a function of relationships between numerous transmitter systems rather than endogenous activity in one isolated system. This and other reviews also demonstrate that different emotions and different forms of the same emotion are mediated in the CNS by partially independent neurophysiological systems (Avis, 1974; Gittelman-Klein, & Klein, 1971; Heiser & DeFrancisco, 1976).

The suggestion that nicotine inhibits muscarinic aggression circuits is consistent with Silverman's (1971) findings showing nicotine's main effect on social behavior in rats to be a reduction of aggression. It also conforms to the fact that in the nicotine studies to date, aggression is the one emotion that has most consistently been reduced. This model does not, however, explain why it is that many smokers report feeling tranquilized by smoking in spite of smoking's ANS-arousal-producing effects.

It can be inferred from Miller's (1973) neurophysiological model that nicotine may reduce both behavioral and subjective indices of emotion by a direct neurophysiological inhibition of the impulse to behave in an emotional manner. It has been suggested (Arnold, 1960) that the impulse to respond to an emotion-producing stimulus is of greater importance in the subjective experience of emotion than is the perception of ANS arousal.

Cortical sedation model. Recently, Eysenck (1973) proposed that the effects of nicotine depend on the degree of arousal in the cerebral cortex: When arousal is high, the effects on the cortex are depressant; when arousal is low, the effects are stimulating. During the highly arousing states that accompany most emotions, cortical arousal is high (Lindsley, 1970); hence, the effects of nicotine on the cortex during emotional states are depressant (i.e., tranquilizing). Decreased cortical arousal is assumed to cause decreased emotion. This model can account for nicotine's tranquilizing properties if one assumes that CNS sedation results in decreased CNS response to and perception of ANS-arousal-related input.

The strongest support Eysenck offered for his hypothesis that nicotine has bidirectional effects on arousal came from Armitage and his co-workers (Armitage et al., 1968; Armitage, Hall, & Sellers, 1969). These researchers found that the effects of nicotine administered to cats and rats at a frequency and dosage per body weight corresponding to human smoking resulted in cortical (EEG and acetylcholine level) and behavioral arousal (lever-pressing rate) in some animals of each species and in tranquilization in others.

The studies mentioned earlier in this review that showed that the effects of smoking and nicotine on cortical activity can be either arousing or depressing provide indirect evidence for Eysenck's hypothesis. Also consistent with this bidirectional view is the finding that nicotine tends to increase sensory detection thresholds when CNS arousal is high, but decreases them when CNS arousal is low (Mendenhall, 1925).

Finally, a behavioral study of Ashton and Watson (1970) offers support for Eysenck's bidirectional model. These researchers found that smokers smoked more when underaroused (resting) and when highly aroused (high-stress situation) than they did when only slightly aroused, which suggests that underaroused subjects smoked for stimulation and overaroused subjects for tranquilization.

Eysenck did not speculate as to what physiological mechanism might underlie the suggested bidirectional effects of nicotine on cortical arousal. He did, however, note that this hypothesis is consistent with the conclusion of Rachman (1969) that arousal is an inverted-U-shaped function of the arousal-producing conditions (Eysenck, 1973, p. 136).

There is very little research that relates directly to Eysenck's hypothesis. A test of this proposal would be to expose subjects to an emotion-producing situation and, after cortical arousal was high, to administer nico-

tine while continuing to monitor CNS indices of arousal.

Interacting CNS mechanisms. A possibility not discussed by Eysenck is that there are two brain arousal systems that interact, so that arousal in one system tends to inhibit arousal in the other system. Routtenberg (1968) has made a strong argument for the likelihood of the existence of two such arousal systems (limbic and reticular activating) and has noted evidence that arousal of either one of these systems leads to cortical arousal but that the simultaneous arousal of both of them leads to cortical tranquility. Consistent with this hypothesis, Barnes (1966) showed that either of two stimulants (eserine or amphetamine) caused EEG arousal (fast waves), but surprisingly, the administration of both reinstated tranquilization (slow wave EEG activity). If emotional arousal is based primarily on the activation of one of these two systems, the tranquilizing properties of nicotine may be a result of the inhibition of this system by nicotine's arousing of the other system. A replication of Barnes's study with nicotine, as well as eserine and amphetamine, would be a test of this hypothesis.

Related to the idea of mutually inhibitory arousal systems are the findings of Friedman, Horvath, and Meares (1974), which showed that tobacco (but not nontobacco) cigarette smokihg significantly increased the rate of habituation of EEG alpha desynchronization to a series of 90-dB sound pulses. These researchers proposed that since theoretical models suggests that habituation depends on active inhibitory and excitatory mechanisms that oppose each other (Sokolov, 1960), it is possible that nicotine causes a dislocation of the usual relationship, so that inhibitory mechanisms are more fully activated without a simultaneous reduction in CNS excitation. This model is consistent with the earlier discussed findings that showed that nicotine increases some measures of cortical arousal while reducing others. It is also consistent with the EEG and self-report data, reviewed earlier, that suggest that nicotine increases the state of mental alertness while simultaneously producing a state of emotional tranquility. This model suggests that nicotine causes an individual first to become aware of, but soon to pay little attention to, emotion-related stimuli, thoughts, and ANS end-organ activity.

Studies that simultaneously monitor CNS indices of arousal and responses to external emotional input would be relevant to this hypothesis. A modified replication of the study by Friedman et al., in which nicotine would be administered intravenously or by other nonsmoking means, would provide a significant amount of credibility to this hypothesis.

Another model has been suggested by Goldstein et al. (1967). It is based on their studies of the effects of nicotine on simultaneous quantitative measures of cortical electrical activity in the rabbit brain. They interpreted their results as indicating that nicotine causes an impressive diminution of mutual involvement (EEG covariance) between the cortex and the hippocampus, and between the cortex and the reticular formation. These findings, they suggested, may imply a decrease in the activity of inhibitory mechanisms operating between cortical and subcortical sites. Thus, for instance, nicotine may relax excessively rigid control by the neocortex of subcortical structures (and vice versa). This model can explain the tranquilizing effects of nicotine if one assumes that either subcortical input to cortical structures or phasic deviation from the ANS-arousal baseline, rather than the baseline itself, determines the intensity of emotional responses. The nicotine from a single cigarette sustains high levels of ANS end-organ arousal for up to 30 minutes. On the other hand, startle responses and many other emotion-related responses that are likely to be mediated by interactions between cortical and subcortical structures usually operate in a much smaller time frame.

Pleasure-center-stimulation models. Eysenck (1973) has suggested an extension of his proposed cortical sedation explanation of nicotine's paradoxical effects. The additional proposal is based on the suggested effects of nicotine on pleasure and aversion systems in the brain. First, granting the very speculative nature of the hypothesis, Eysenck started by reminding the reader that three

different hedonic systems have been described (Berlyne, 1971; Olds & Milner, 1954; Olds & Olds, 1965). The first two are the primary reward and aversion systems; the stimulation of either of these leads to familiar signs of increased arousal, including increased heart rate, high-frequency EEG waves, and increased bodily movement; the third is the secondary reward system, the activation of which results in de-arousal. It is suggested that the secondary reward system produces rewarding effects indirectly, that is, by inhibiting the aversion system, which in turn releases the primary reward system from inhibition by the aversion system. Eysenck (1973, p. 140) proposed that nicotine administered in emotionally arousing situations may activate the secondary reward system and through it deactivate the aversion system. On the other hand, he also suggested that in low-arousal situations nicotine may activate the primary reward system directly. Eysenck offered no direct support for this model, but did note that it is open to experimental falsification.

In contrast with Eysenck's hypothesis, the model proposed by Jarvik (1970, 1973) assumes that nicotine's emotion-reducing properties are a product of its presumed ability to stimulate primary rather than secondary reward centers. Nicotine, like amphetamine, is assumed to release stores of norepinephrine and other catecholamines in primary reward areas of the brain such as the medial forebrain bundle, the results being an improvement in mood and a reinforcement of behavior associated with the administration of the drug. This interpretation is consistent with the catecholamine theory of emotion (Schildkraut & Kety, 1967), which assumes that catecholamine activity in the brain, particularly norepinephrine activity but possibly also dopamine and epinephrine activity, is responsible for sustaining positive affect. The pleasure-center-stimulation model can be inferred to assume that a hedonic process is an important component of emotion and that nicotine's purported pleasure-increasing properties more than compensate for its ANS-arousing properties.

Jarvik's and, to a lesser extent, Eysenck's hypotheses are not supported by the finding (Schuster, 1970) that amphetamine increased rather than decreased cigarette-smoking frequency in habitual smokers. In his discussion of these findings, Schuster pointed out that it is difficult to understand why smoking increased, since one assumes that there is at least some satiation of the central reward mechanisms by amphetamine, leading to a diminished need for nicotine intake.

On the other hand, support for the pleasure-center-stimulation model is given by findings that suggest that nicotine releases acetylcholine in the brain (Armitage, 1973; Essman, 1973; Knapp & Domino, 1962). Finally, Armitage (1973) has said that the findings of a recent study by G. H. Hall and Turner (1972) suggest that nicotine does in fact release noradrenaline in the specific areas of diencephalic pleasure centers, thus providing an important link to Jarvik's (1970, 1973) hypothesis that nicotine produces its effects by stimulating pleasure centers in the brain and causing or facilitating the release of catecholamines in these centers. With cats, intravenously injected nicotine (.002 mg/kg every 30 sec) caused an increased release of ^{3}H-noradrenaline into the effluent of the third cerebral ventrical, as did the administration of cigarette smoke directly into the lungs.

Also consistent with the pleasure-center-stimulation model, but inconsistent with arousal formulations of emotion, is that amphetamine, a CNS and ANS stimulant that also appears to stimulate pleasure centers (Jarvik, 1970, p. 188; Ray, 1972, p. 167), causes subjective assessments of relaxation that are far in excess of responses relating to nervousness (Martin, Sloan, Sapira, & Jasinski, 1971). Furthermore, it is a well-accepted fact that amphetamine, methylphenidate, and other CNS stimulants have paradoxical tranquilizing effects on hyperactive children (Satterfield, Cantwell, & Satterfield, 1974) and on some adults who manifest overreactivity and other symptoms of the hyperactive syndrome (Wood, Reimherr, Wender, & Johnson, 1976). Finally, small doses of amphetamine have been shown to frequently reduce aggression in laboratory animals, whereas large doses have been

shown to increase it (for a review, see Allen, Safer, & Covi, 1975).

In summary, several findings are consistent with the hypothesis that nicotine's emotion-reducing properties are at least partially a function of its suggested ability to stimulate CNS pleasure centers. The findings of G. H. Hall and Turner (1972) offer some direct evidence suggesting that nicotine stimulates pleasure center activity. However, the question of whether this increment in activity increases pleasure, whether nicotine increases such activity during emotional states, and whether such activity is related causally or only correlationally to reduced emotions have not been investigated. Amphetamine appears to stimulate pleasure centers and, like nicotine, reduces several indices of anxiety and aggression, which suggests that there may be a causal relation between pleasure and the inhibition of emotions. However, a great deal of further investigation is needed before an accurate assessment of the pleasure-center-stimulation model can be made.

Mechanisms Based on Altered Perceptions of Peripheral Activity

One of the three mechanisms based on altered perceptions of bodily activity discussed below may account for nicotine's reduction of emotions in spite of increased ANS activity. The first of these mechanisms is based on the findings of Wenusch and Schöller (1936) and Mendenhall (1925), which showed an increase in the detection threshold for electrical shock following the smoking of a regular tobacco cigarette but not following the smoking of a nicotine-free cigarette. These results suggest that such smoking-induced increases of sensory thresholds may decrease subjects' awareness of their autonomic arousal in spite of an actual increase in ANS activity. If emotion is more a function of consciously perceived than of actual autonomic arousal, then the paradox is resolved. This model makes no assumptions as to whether the elevation in threshold is caused by a general cortical sedation similar to that suggested by Eysenck (1973) or whether it is a result of some more specific process such as that suggested by the neurophysiological model discussed earlier in this review.

The second of the proposed mechanisms based on altered perceptions of bodily activity assumes that nicotine's tranquilizing properties are a consequence of muscular-action-reducing properties of nicotine. Research shows that while nicotine increases ANS arousal, it reduces reflexive muscular activity (patellar and startle responses) in humans and primates (Domino, 1973; Hutchinson & Emley, 1973) and reduces resting muscle tone levels in spastic patients (Webster, 1964). Hence, it may be that people who report that smoking tranquilizes them attend to muscular changes, the tranquilizing effects of which overshadow the effects of smoking-induced increases of autonomic arousal. It appears that the subjective experience of emotion is a positive function of facial and skeletal muscular activity as well as of ANS arousal. If this hypothesis is true, nicotine can be expected to reduce emotions with a large muscular component more than those with a relatively greater autonomic arousal component.

The final of the three proposed mechanisms was suggested by Schachter (1973, p. 152) in a direct attempt on his part to explain the paradoxical tranquilizing effects of smoking. This mechanism is based on the *law of initial values*, the finding that "the magnitude of response is related to prestimulation level" in such a manner that "high autonomic excitation preceding stimulation is correlated with low autonomic reactivity upon stimulation" (Lacey, 1956, p. 156). The argument is that since nicotine leads to arousal, the additional arousal induced by an emotional situation is less with nicotine than without it. If the intensity of an emotion is a positive function of the deviation of autonomic activity from its baseline, this explanation is plausible. At the present time, however, there appear to be no data either strongly in support of or contrary to this ANS deviation model of emotion.

Altered Cue Value of Peripheral (Bodily) Activity

It may be possible to feel physiologically aroused and yet feel unemotional and tranquil. Schachter (1973), in the same article in which he proposed the law-of-initial-values solution to the paradox, noted the possibility of an alternative model. This alternative assumes that habitual smokers experience their body as reacting with the same sympathetic symptoms when they smoke as it reacts when they experience an emotion; therefore, to the degree that they attribute their bodily arousal to smoking, they should be less emotional; that is, in an emotional situation a smoker feels emotion only to the degree that arousal (both emotional stimulus induced and nicotine induced) is attributed by the person to an emotional stimulus. To the degree that arousal is attributed to smoking (or other nonemotional sources), emotion is not felt (i.e., there is tranquilization). Unfortunately, this proposal by Schachter seems unlikely to be a general solution to the paradox, since subhuman species with little or no experience with nicotine show reductions of emotional behavior and it appears that there is no reason for such animals to attribute their arousal to a source other than the emotion-producing stimulus.

Impulse Reduction Model

It may be that a person can feel autonomic arousal and yet feel relaxed, tranquil, and unmotivated. This model does not assume, as does Schachter's, that misattribution of arousal to a nonemotional source is the critical step; nor does the model require prior experience with nicotine. Instead, it suggests that nicotine may reduce the motivation, the impulse-to-move component of the emotional complex, possibly in a manner similar to the unexplained mechanism by which morphine reduces pain. Ray (1972) has noted that many laboratory reports suggest that morphine has no effect on pain threshold and that it does not impair conduction in peripheral nerves. Following the administration of an analgesic dose of morphine, some patients report that they still notice pain but that it is no longer aversive; nor does the pain demand attention or an impulse to action (Ray, 1972). Similarly, nicotine may not alter or may actually increase the subjective perception of ANS arousal, yet may decrease the attention an individual gives these symptoms and may reduce the impulse to respond to this bodily activity and to external emotion-producing stimuli.

A reduction of the impulse to respond to the emotion-producing stimulus would result in lessened behavioral measures of emotion and, according to Arnold's (1960) well-known theory of emotion, would reduce subjectively experienced emotion as well, since Arnold argued that emotion is best conceived of as the felt urge toward or away from an object perceived as good or bad. Furthermore, studies showing that nicotine reduces emotional muscular reflexes in man and monkeys (Domino, 1973; Hutchinson & Emley, 1973) are consistent with this impulse reduction model, as is Miller's (1973) neurophysiological hypothesis of antagonistic nicotinic and muscarinic neural systems, which was discussed earlier. Finally, the recent discovery of naturally occurring opiatelike substances (endorphins and enkephalins) in the brain and their reported emotion-reducing effects (Arehart-Treichel, 1978) adds to the plausibility of this mechanism.

Glucocorticoid–ACTH Model

It is possible that nicotine's emotion-reducing effects are mediated by the nicotine-induced release of glucocorticoids from the cortex of the adrenal gland. Glucocorticoids have been reported to reduce a variety of indices of emotion (Di Giusto, Cairncross, & King, 1971; Endroczi, Lissak, Fekete, & DeWied, 1970; Levine, 1971), and nicotine, in small, smoking-sized doses, has been shown to cause increased serum levels of glucocorticoids (Hill & Wynder, 1974; Kershbaum, Pappajohn, & Bellet, 1968). These two facts suggest that nicotine-induced reductions of emotional reactions are mediated and caused by nicotine-induced increases in serum glucocorticoids. Furthermore, nicotine and glucocorticoids have parallel effects on the following indices of

emotion, sensory detection threshold, and higher cognitive functions:

1. They reduce measures of emotion (Di Giusto et al., 1971; Levine, 1971; Schechter & Rand, 1974; Silverman, 1971).
2. They reduce startle responses (Hutchinson & Emley, 1973; Levine, 1971).
3. They facilitate habituation of the EEG alpha-desynchronization orienting response (Endroczi et al., 1970; Friedman et al., 1974).
4. They increase sensory detection thresholds (Henkin, 1970; Mendenhall, 1925).
5. They increase higher integrative functioning such as memory, learning, discrimination, and accuracy (Andersson & Post, 1974; Geller, Hartmann, & Blum, 1971; Henkin, 1970; Levine, 1971; Myrsten et al., 1972; Nelsen & Goldstein, 1972).

Indirect support for the glucocorticoid model is provided by evidence suggesting that nicotine's emotion-reducing and cognition-facilitating effects occur maximally 15 to 45 minutes after the administration of nicotine (Andersson, 1975; Andersson & Post, 1974), at the same time at which nicotine-induced glucocorticoid blood levels are highest (Hill & Wynder, 1974).

It should be noted that glucocorticoid levels in the blood interact in a complex manner with ACTH levels and sex hormones and that these hormones have been shown to influence indices of emotion and learning (Di Giusto et al., 1971; Leshner et al., 1973; Levine, 1971). Since ACTH from the pituitary gland stimulates secretion of glucocorticoids from the adrenal cortex, it seems likely that nicotine increases glucocorticoid levels by increasing blood levels of ACTH. If nicotine in fact does increase blood levels of ACTH, it would be of significance, since ACTH has been shown to reduce aggressiveness in mice (Leshner et al., 1973). Therefore, it may be more appropriate to consider a general pituitary, adrenal model of the emotion-reducing effects of nicotine.

Summary and Conclusions

A number of contemporary theories of emotion assume that emotions are largely a positive function of ANS arousal. However, a substantial number of studies have shown that nicotine increases heart rate, blood pressure, and numerous other indices of autonomic arousal; yet rather than producing expected increases of emotional behavior and feelings, it usually decreases emotions. A more detailed analysis reveals that the effects of nicotine on physiology and emotions are quite complex. First, nicotine typically increases ANS arousal, but the findings of one investigation suggest that this increase may depend on predrug arousal level. Likewise, nicotine's effects on classical CNS measures of arousal have typically been in the direction of increased arousal, while its effects on more specific and sophisticated CNS indices have been mixed and have depended on such factors as individual differences, rate of nicotine administration, and locus of brain activity monitored. One must question the relevance of the studies to date on the effects of nicotine on CNS activity, since they have not used emotionally aroused subjects, but have maintained subjects in pre- and postnicotine states of low arousal and inactivity. There is an obvious need for a systematic series of studies that monitor a variety of CNS, ANS, and muscular indices while manipulating and controlling personality, time, arousal, emotional, and drug parameters.

In spite of the fact that several indices of emotion have consistently been reduced by the administration of nicotine, the question as to whether all types and intensities of emotion are reduced has not been answered. It seems likely that nicotine's emotion-reducing effects vary from emotion to emotion, across various indices of the same emotion, and with a variety of other factors. The systematic investigation of the effects of nicotine on the whole spectrum of emotional dimensions could add significantly to the understanding not only of nicotine's paradoxical effects but also of emotional processes in general.

A number of mechanisms that may account for nicotine's paradoxical tranquilizing effects have been proposed, but none are backed by a convincing network of supportive data. It seems evident that aside from

a serendipitous major breakthrough, a great number of studies testing a large variety of proposed theories will be needed before the mechanism or mechanisms underlying the paradox are determined. Different proposed mechanisms are not necessarily mutually exclusive. The impulse reduction model, for example, is an attempt to integrate several low-level mechanisms into a higher order or more complete picture of the emotion-reducing properties of nicotine. This model is consistent with muscular-tension-reduction, pleasure center, and neurophysiological models, but adds a higher level of conceptual integration that allows one to see that the research on nicotine and emotions is consistent with Arnold's (1960) impulse theory of emotions, whereas it is inconsistent with many other conceptions of emotion.

The literature surveyed in the present review suggests that the mechanism(s) by which nicotine reduces emotion is influenced by a wide variety of variables, including behavioral activity level, CNS arousal level, personality, type of emotion, time since administration of drug, and rate and dose of nicotine administration. Any mechanism that is suggested to fully explain nicotine's tranquilizing properties must account for the influence of these variables; but unfortunately, of the mechanisms reviewed earlier, only Eysenck's (1973) proposal attempts to deal with their contribution. The most promising approach for future research would seem to be for studies to systematically manipulate and control these influential variables in evaluations of a spectrum of suspected lower and higher order mechanisms. A major first step would be the development of a paradigm with specific parameters that reliably demonstrates the nicotine-induced reductions of emotion. Once this paradigm has been established further studies can vary its potentially influential variables, thus contributing to a clearer understanding of the drug's paradoxical effects.

History of the Sleeper Effect: Some Logical Pitfalls in Accepting the Null Hypothesis

Thomas D. Cook
Northwestern University

Charles L. Gruder
University of Illinois at Chicago Circle

Karen M. Hennigan and Brian R. Flay
Northwestern University

The history of research on the sleeper effect prior to 1978 can be divided into five stages: (a) initial discovery of the effect, (b) development of the underlying theory, (c) widespread acceptance of the effect and of the discounting cue explanation of it, (d) realization that past operational definitions of the effect were not isomorphic with the conceptual definition, and (e) repeated failures to demonstrate the effect once operational definitions were employed that corresponded to the conceptual definition (Gillig & Greenwald, 1974). These failures resulted in an invitation to accept the null hypothesis and to "lay the sleeper effect to rest." This article illustrates why it is not justifiable to accept the null hypothesis about the sleeper effect. We suggest that provisional acceptance of the null hypothesis depends on assuming that all the necessary theoretical, countervailing, statistical, and procedural conditions for an adequate test of the effect have been demonstrably met. We further suggest that none of the empirical studies prior to 1978 demonstrably succeeded in meeting these conditions. However, adequate tests following the guidelines we have described for provisionally accepting the null hypothesis have recently been conducted, and the effect has been repeatedly found. A deductive model of the logical factors that should guide provisional acceptance of the null hypothesis is contrasted with a current model that stresses induction and statistical power analyses.

Most statistics texts assert that there is no formal basis for accepting the null hypothesis. The rationale for this assumption is basically a restatement of the well-known position in philosophy that inductive knowledge is not logically possible. However, practicing scientists are often forced to act as though the null hypothesis were true even when they know that there is no compelling epistemological basis for their actions. Given the apparent conflict between practice and logic, it is important in the analysis of research findings to be clear about the criteria that help distinguish between a conclusion such as "We can be reasonably certain that no meaningful difference exists" and a conclusion such as "Although no statistically reliable difference was found, we cannot be at all certain whether a meaningful difference exists."

The present article uses the history of research on the sleeper effect to illustrate some pitfalls in accepting the null hypothesis. It also uses this research to describe and justify a model that might help in deciding when no-difference findings warrant the tentative conclusion that no difference exists as opposed to the conclusion that no decision about differences is warranted. The sleeper effect is useful for this illustration, since a recent claim was made that the effect does not exist (Gillig & Greenwald, 1974) despite 25 years of claims that it does. The claim

Karen M. Hennigan is now at the University of Southern California, and Brian R. Flay is now at the University of Waterloo, Waterloo, Canada.
The authors would like to thank Anthony G. Greenwald and Daniel Romer for their comments on a previous draft of this article.
Requests for reprints should be sent to Thomas D. Cook, Department of Psychology, Northwestern University, Evanston, Illinois 60201.

that the effect does not exist was based on a particular model for "How to Accept the Null Hypothesis Gracefully" (Greenwald, 1975, p. 16). However, since subsequent research guided by a quite different model has led to repeated discoveries of the sleeper effect (Gruder, Cook, Hennigan, Flay, Alessis, & Halamaj, 1978), it may be useful to detail the later model here and to contrast it with the earlier model.

To accomplish our ends we first review the history of research on the sleeper effect, for no detailed review yet exists in the literature. Then we outline the requirements for an adequate test of the null hypothesis, using the sleeper effect as an illustration. After this, we examine whether the failures to obtain sleeper effects prior to 1978 were due to the phenomenon's not existing or were due to inadequate tests, and we conclude that no conclusion on this issue was warranted prior to 1978. Next we report the results of two studies that repeatedly obtained sleeper effects when the necessary conditions for the phenomenon were demonstrably met and did not obtain them when these conditions were not met. Finally, we compare and contrast two models for tentatively accepting the null hypothesis.

History of the Sleeper Effect

In 1949, Hovland, Lumsdaine, and Sheffield reported an experiment that was designed to evaluate the impact of a World War II propaganda film on soldiers' beliefs.[1] The experimental design was a 2×2 factorial: Enlisted soldiers did or did not see the film, and their message-relevant beliefs were measured 5 days or 9 weeks afterward. The authors focused their discussion on a subset of eight items in which belief changed little initially and in which the difference between the experimental and control groups was larger after 9 weeks than it was after 5 days. This difference of differences was interpreted as "raising the possibility of a 'sleeper' effect" because it seemed that the full impact of the film took time to build up.

The authors proposed four general hypotheses to explain the effect. The one that has been most cited was called the *discounting cue hypothesis*. It specified (a) that the army, which sponsored the film, was seen as a biased and therefore untrustworthy source for war-relevant information; (b) that its sponsorship of the film led the soldiers to initially discount the filmed message, thereby reducing its immediate impact on their beliefs; (c) that as time passed the source of the message was forgotten or dissociated from the message, thereby removing the change-inhibiting force of the untrustworthy source; and (d) that once the source was no longer linked to the message, soldiers' attitudes rose to the residual level of belief change caused by the message alone. This reasoning suggests a possible explanation of why sleeper effects occurred for only a subset of the belief items in Hovland et al.'s study: The message's initial effectiveness may not have totally dissipated over 9 weeks for these items, but it may have totally dissipated for the other items.

It should be noted that the term *sleeper effect* can be used in a general sense to describe a delayed increase in any dependent variable, not just in belief. Even in persuasion research there is no need to restrict the term to contexts in which the discounting cue hypothesis is invoked as an explanation. Indeed, three of the four explanations that Hovland et al. (1949) offered of their sleeper effect did not even mention a discounting cue. Nonetheless, many commentators in social psychology seem to use the term *sleeper effect* to refer to both the descriptive phenomenon (a delayed increase in belief change) and a particular explanation (the discounting cue hypothesis). We also use the term in this traditional way.

Development of the Theory and Replications of the Sleeper Effect

Three experiments were designed to replicate the sleeper effect and to directly test

---

[1] In the social psychological literature on persuasion, the terms *attitude* and *belief* have often been used interchangeably, although their definitions have been distinguished. Since most studies that we cite measured beliefs, we use this term exclusively in this article, although we recognize that in certain cases attitude may be the appropriate term.

and extend the discounting cue explanation of it. Hovland and Weiss (1951) manipulated whether persuasive messages came from sources of high or low credibility, with low credibility serving as a discounting cue. They claimed that a sleeper effect resulted in the low-credibility condition. Since data indicated that the low-credibility sources had probably not been forgotten, they explained the effect in terms of the message and source being spontaneously dissociated from one another with the passage of time.

Weiss (1953) followed this research by having subjects learn a persuasive message that was or was not linked to a brief statement that discounted the message. Weiss claimed to have found a sleeper effect with this particular discounting cue manipulation, although he carefully pointed out that his inference was based on there being relatively less decay of change when the discounting cue was learned than when it was not. He did not find an absolute increase in belief change in the discounting cue condition.

Kelman and Hovland (1953) had subjects learn a persuasive message from a source of high or low credibility, and the source was or was not reinstated at the delayed testing 2 weeks later. When no reinstatement took place, the data pattern resembled that of Hovland and Weiss: Belief change appeared to increase with time in the low-credibility condition and to decrease with time in the high-credibility condition. But when reinstatement took place (reversing any dissociation that might have occurred) neither the increase in change in low credibility nor the decrease in change in high credibility was obtained.

Kelman and Hovland reasoned from these data that the process of belated dissociation of the message and the cue applies both to cues that cause initial rejection of a message and to cues that enhance a message's initial impact. But while the dissociation of discounting cues should facilitate sleeper effects, the dissociation of message-acceptance cues should accelerate the decay of initial belief change. Kelman and Hovland coined the term *dissociative cue hypothesis* to refer to the common process of first associating and then dissociating message-acceptance or message-rejection cues from a message. Seen from this perspective, the discounting cue hypothesis is a special case of the more general dissociative cue hypothesis.

Widespread Acceptance of the Sleeper Effect

These theory-testing experiments in which sleeper effects were found were followed by many other apparent replications that were reported in the literature from 1953 through the early 1970s. As a result of these repeated replications, numerous textbooks referred both to the validity of the effect and to the validity of the discounting cue explanation of it.

The studies that led to such widespread acceptance of the sleeper effect are reviewed below. We define a discounting cue as any brief item of information that leads a reader to summarily reject the conclusion of a persuasive message and so inhibits the immediate belief change that the message would otherwise cause. The predominant manipulation of a discounting cue has been to have the message come from a communicator of low credibility (Falk, 1970; Gillig & Greenwald, 1974; Hovland & Weiss, 1951; Johnson, Torcivia, & Poprick, 1968; Johnson & Watkins, 1971; Kelman, 1958; Kelman & Hovland, 1953; Schulman & Worrall, 1970; Watts & McGuire, 1964; Weber, 1972; Whittaker & Meade, 1968; Weber, Note 1). But other operationalizations included a brief countercommunication (Weiss, 1953), qualifying statements that questioned the validity of the arguments within the message (Papageorgis, 1963), a countermessage presented once while the persuasive message was repeated three times (Wilson & Miller, 1968), and forewarning that a contrary message existed (Holt & Watts, 1973). We consider all these experiments as relevant to the sleeper effect, though Wilson and Miller and Papageorgis did not specifically mention the discounting cue hypothesis in their reports. (Adding these experiments to the review makes little or no difference to the general conclusions.)

The operational definition of the sleeper effect employed in most studies before the mid-1970s was an interaction of time of test-

ing (immediate vs. delayed) and whether the persuasive message was or was not associated with a discounting cue. For reasons that become clear later, we call this operationalization a relative sleeper effect.

The results of 16 experiments that permitted a test of the relative sleeper effect are presented in columns 2 and 3 of Table 1. Of these studies, 11 resulted in at least marginally significant relative sleeper effects. Thus, the preponderance of the evidence does indicate that the relative sleeper effect is a reliable phenomenon.

However, it should be noted that the absolute values of the slopes of the time trends were typically higher in the experimental conditions without discounting cues than they were in the conditions with them. In other words, decay in the nondiscounting conditions contributed more to the interactions than did any delayed increase in the discounting conditions. This observation raises an important question concerning the fit between the operational and conceptual definitions of the sleeper effect.

Realization That Past Operational Definitions Did Not Match the Conceptual Definition of a Sleeper Effect

Careful reading of early accounts suggests that the crucial defining attribute of a sleeper effect is an absolute increase in belief change over time. For instance, Hovland et al. (1949) summarized their data by stating, "Some of the effects of the film may be 'sleepers' that do not occur immediately but require a lapse of time before the full effect is evident" (p. 188). McGuire (1969) described the same findings as indicating that "the impact of . . . the film was greater after eleven weeks had passed [from the pretest, not the film] than it had been shortly after the showing of the film" (pp. 254–255). In the context of manipulations of low credibility, Insko (1967) wrote, "This increase in the influence of the low credibility source over time was called the 'sleeper effect'" (p. 44).

An operational definition that closely corresponds to the conceptual definition is that there is more belief change at a delayed

Table 1
Outcomes of Past Experiments Classified According to Definition of the Sleeper Effect

	Relative sleeper		Absolute sleeper	
Study	Statistically significant?	Condition with higher slope value	Appropriate direction?	Statistically significant?
Hovland & Weiss (1951)	Yes	Nondiscounting	Yes	DK
Kelman & Hovland (1953)	Yes	Nondiscounting	Yes	No
Kelman (1958)	DK	Discounting	Yes	DK
Watts & McGuire (1964)	Marginal	Nondiscounting	No	
Johnson, Torcivia, & Poprick (1968)	No	Discounting	No	
Whittaker & Meade (1968)	Yes	Nondiscounting	No	
Falk (1970)	Yes	Nondiscounting	Yes	No
Schulman & Worrall (1970)	Yes	Nondiscounting	No	
Johnson & Watkins (1971)	Yes	Nondiscounting	No	
Weber (Note 1)	No	Discounting	No	
Weber (1972)	Yes	Nondiscounting	Yes	Yes
Gillig & Greenwald (1974)	Yes	Nondiscounting	Yes	No
Weiss (1953)	Yes	Nondiscounting	No	
Papageorgis (1963)	No	Nondiscounting	Yes and no	DK
Wilson & Miller (1968)	NA	NA	Yes in 6 of 8 comparisons	DK
Holt & Watts (1973)	Yes	Nondiscounting	Yes	Yes

Note. DK = do not know—cannot be computed from the available data; NA = not appropriate—there was no equivalent to a message-acceptance or message-only condition.

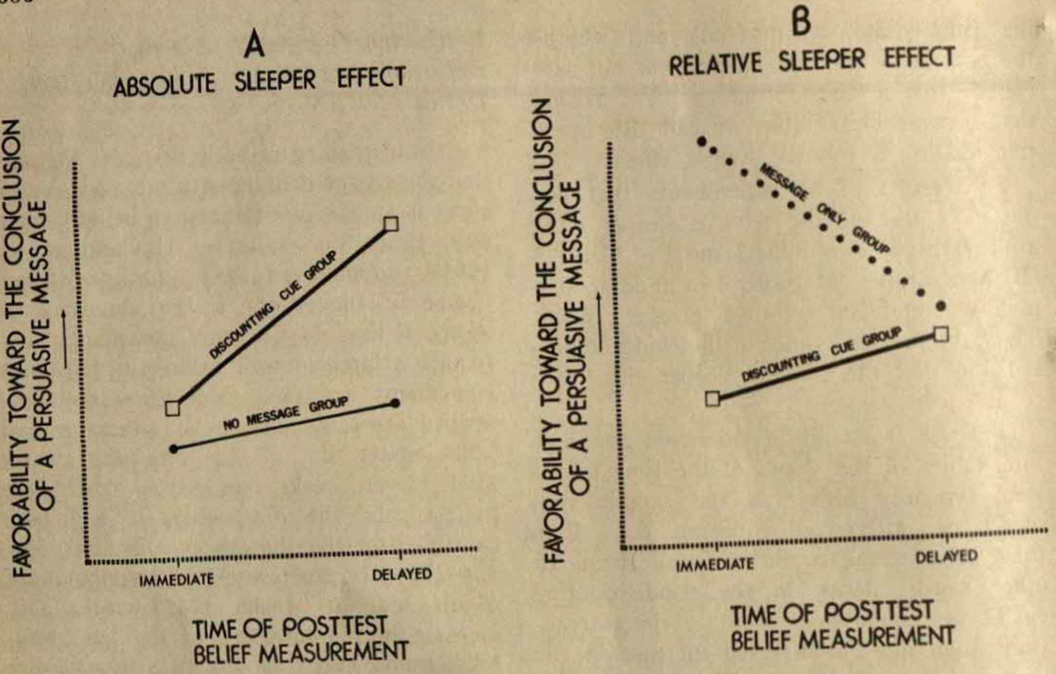

Figure 1. Hypothetical illustrations of absolute and relative sleeper effects.

belief-testing session than at a session immediately after the learning of a message (see the upper line in Figure 1A). However, an implicit assumption of this definition is that beliefs would stay constant over time if there were no persuasive message. To control for the possibility of shifting population beliefs, it is desirable to collect data from no-message controls—subjects who have not received the persuasive message (see the lower line in Figure 1A). A second operational definition of a sleeper effect is that the pattern of posttest beliefs should suggest more of an increase in belief change (or less of a decrease) in a discounting cue group than in a no-message control group. With only two posttest time intervals, a sleeper effect would be indicated by a difference of differences or by an interaction of groups (discounting cue vs. no message) and the time of posttest measurement (immediate vs. delayed). With more delay intervals, differences between time trends would be used for inferring the effect.

In the past, the sleeper effect has often been defined as less decay, or relatively more change over time, in a discounting cue group relative either to a group exposed to the persuasive message alone (message-only controls) or to a group in which the message is linked to a cue that should increase acceptance of the message conclusion (see Figure 1B). These operational definitions rest on the assumption that the decay of initial belief change in the message-only or message-acceptance groups is an accurate estimate of the decay that would result in a discounting cue group if there were no sleeper effect. This assumption is difficult to accept because there is usually more initial change in the comparison groups than in a discounting cue group, and greater subsequent decay is usually associated with large initial changes (Cook & Flay, 1978). Therefore, defining the effect relative to these comparison groups overestimates the expected decay in discounting cue groups, and false positive sleeper effects can be inferred. It is likely that too many false positives were inferred in the past because more initial change was obtained in the groups without discounting cues and because the absolute decay of change found in these groups was more than the absolute increase in change found in the discounting cue groups. In other words, a statistical interaction between time of measure-

ment and experimental groups (a discounting cue group and a message-acceptance or message-only group as the comparison group) was taken as evidence of the effect. These interactions typically resulted from relatively less decay in a discounting cue group rather than from an absolute increase in change, which is what the conceptual definition calls for.

Consideration of the lack of fit between past conceptual and operational definitions of the sleeper effect led Cook (Note 2) to coin the term *relative sleeper effect* to refer to the statistical interaction between experimental groups (one of which receives a message plus a discounting cue, while the other receives the same message without a cue) and time of testing (one test coming immediately after the message and the other after a delay period). Since a relative sleeper effect does not correspond closely to the conceptual definition of a sleeper effect, Cook also coined the term *absolute sleeper effect* to refer to more appropriate operational definitions, namely, a temporal increase in belief change within a discounting cue group or a relatively greater increase in this group when compared with a no-message control group.

There are two special situations in which it is not appropriate to test the absolute sleeper effect in the way we have just outlined. First, the effect would not be validly tested if a discounting cue were so strong that instead of merely inhibiting initial attitude change, it caused attitudes to change significantly in the opposite direction (i.e., it caused a "boomerang effect" to below the no-message baseline). In such cases, one could not distinguish whether any obtained sleeper effect reflected (a) reversion over time toward the no-message baseline, (b) reversion over time toward a level equal to the delayed impact of the message when the message and cue are dissociated, or (c) both forces operating simultaneously. One must, therefore, be careful to inspect immediate belief means lest boomerang effects create spurious sleeper effects or inflate the estimates of true ones. Second, it would be difficult to accept a discounting cue interpretation of an absolute sleeper effect if subjects in a discounting cue group were more favorable to the message conclusion at the delayed posttest than were subjects in a message-only group (i.e., if there were a significant "crossover effect"). This is because the discounting cue hypothesis predicts that after dissociation, belief change in a discounting cue group will increase over time to the level found in a message-only group and not beyond this level. Though it would warrant theoretical and empirical exploration, a significant crossover would be inconsistent with the discounting cue explanation of an obtained absolute sleeper effect.

Failure to Demonstrate the Absolute Sleeper Effect

Prior to 1978, there was only one systematic attempt to test directly for an absolute sleeper effect: Greenwald and Gillig (Note 3) reported their failure to obtain the effect in five experiments and later published an article based on seven unsuccessful replication attempts (Gillig & Greenwald, 1974). In the title of this latter article they rhetorically asked "Is It Time to Lay the Sleeper Effect to Rest?" (Gillig & Greenwald, 1974, p. 132). Their work explicitly acknowledged an earlier version of the present article (Cook, Note 2), in which past experiments were reviewed to see if any conclusions about absolute sleeper effects were warranted. However, no review of this issue has yet appeared in print, and so we briefly offer one here.

There are some difficulties, however, in ascertaining whether past studies resulted in absolute sleeper effects. First, few of the past experiments included statistical tests of the appropriate effect. We have therefore tried to conduct the missing absolute tests ourselves, using estimates of the means and standard errors that were either cited in published reports or that we were able to compute for ourselves from other published information. In three cases, the information was insufficient for computing any direct test of the absolute sleeper effect (Hovland & Weiss, 1951; Kelman, 1958; Wilson & Miller, 1968). Second, some research reports contained relevant data for more than one discounting cue condition (e.g., Hovland and

Weiss had four low-credibility groups), whereas other reports contained data from more than one relevant experiment (e.g., Gillig & Greenwald, 1974). Our strategy in such cases was to examine the data at their lowest level to see if absolute sleeper effects could be tested at that level. Where there were no statistical (or obvious visual) differences across conditions or experiments, we summed over the various discounting cue conditions, and only the summary data are presented here.

Column 4 of Table 1 indicates whether trends in the discounting cue group were in the direction required for an absolute sleeper effect. Column 5 shows whether the effect was statistically significant. Of the 12 experiments with low-credibility manipulations, 6 had trends in the appropriate direction, 4 of which could be statistically tested. None of the trends reached conventional levels of statistical significance. Of the 4 experiments with other discounting cue manipulations, Weiss's (1953) trend was not in the required direction; Papageorgis (1963) obtained the required trend over 14 days but not over 41 (the 14-day trend could not be statistically evaluated); Wilson and Miller (1968) seem to have obtained the appropriate trends in some of their conditions, but statistical evaluation was again impossible; Holt and Watts (1973) obtained a statistically significant effect.

All in all, there is still no convincing evidence of absolute sleeper effects where low source credibility was the discounting cue. The evidence looks more promising with the other manipulations, but two facts have to be remembered about them. First, the Wilson and Miller experiment was not conceived as relevant to the discounting cue hypothesis; we have made the connection. Second, Holt and Watts found a marginal trend that indicated that subjects in the discounting cue group recalled more of the message both immediately after its presentation and 1 week later. Although the absence of a simple relationship between message learning and the persistence of attitude change (Cook & Flay, 1978) suggests that learning factors might not have mediated the absolute sleeper effect that these authors obtained, it would be more comforting if the discounting cue had not been confounded with marginally greater initial learning and subsequent retention of the message.

In the face of the preponderance of evidence from the past experiments reviewed here and their own seven failures to find an absolute sleeper effect, Gillig and Greenwald (1974) invited readers to accept the null hypothesis that there is no (absolute) sleeper effect. This invitation has not gone unheeded, and recent textbooks have begun to reflect skepticism about the validity of the sleeper effect (e.g., Baron & Byrne, 1977; Oskamp, 1977; Schneider, 1976). To assess whether it is warranted to accept the null hypothesis in this instance, we first discuss the logical requirements for accepting the null hypothesis and then apply this logic to the case of the sleeper effect.

Logic of Provisionally Accepting the Null Hypothesis

Statistics texts teach that it is logically impossible to accept the null hypothesis. However, practical concerns demand that one sometimes provisionally act as though the null hypothesis were true. We believe that there are some guidelines that help in determining when no-difference findings warrant tentative acceptance of the null hypothesis. These are as follows: (a) when the theoretical conditions necessary for the effect to occur have been explicated, operationalized, and demonstrably met in the research; (b) when all the known plausible countervailing forces have been explicated, operationalized, and demonstrably ruled out; (c) when the statistical analysis is powerful enough to detect at least the theoretically expected maximum effect at a preordained alpha level; and (d) when the manipulations and measures are demonstrably valid.

Theoretical Conditions Necessary for the Effect to Occur Must Be Met

Scientific propositions about the existence of a phenomenon are not adequately tested if the theoretical conditions necessary for the phenomenon are absent from empirical

tests. In the case of the sleeper effect, one therefore has to explicate the underlying theory—the discounting cue hypothesis—to determine when it predicts that absolute sleeper effects should occur.

Examination of the discounting cue hypothesis reveals that sleeper effects are only expected under certain conditions. These conditions can perhaps best be understood by considering Figure 2. It shows belief at three different posttest time intervals (immediate and two different delays) in a discounting cue group, a message-only group, and a no-message control group. The figure has been drawn to illustrate the case in which (a) the message causes initial belief change, (b) this change either decays at a continuous rate (the dashed line) or does not decay at all (the dotted line), (c) the discounting cue suppresses all initial belief change (point *A*); and (d) population beliefs do not shift over time (see the solid line for the no-message control group).

Consider what would happen if the message and the discounting cue became dissociated some time before Posttest 2 (delayed). Imagine first that there was no decay of change in the message-only condition (the dotted line). Then, the theory predicts that after dissociation, belief in the discounting

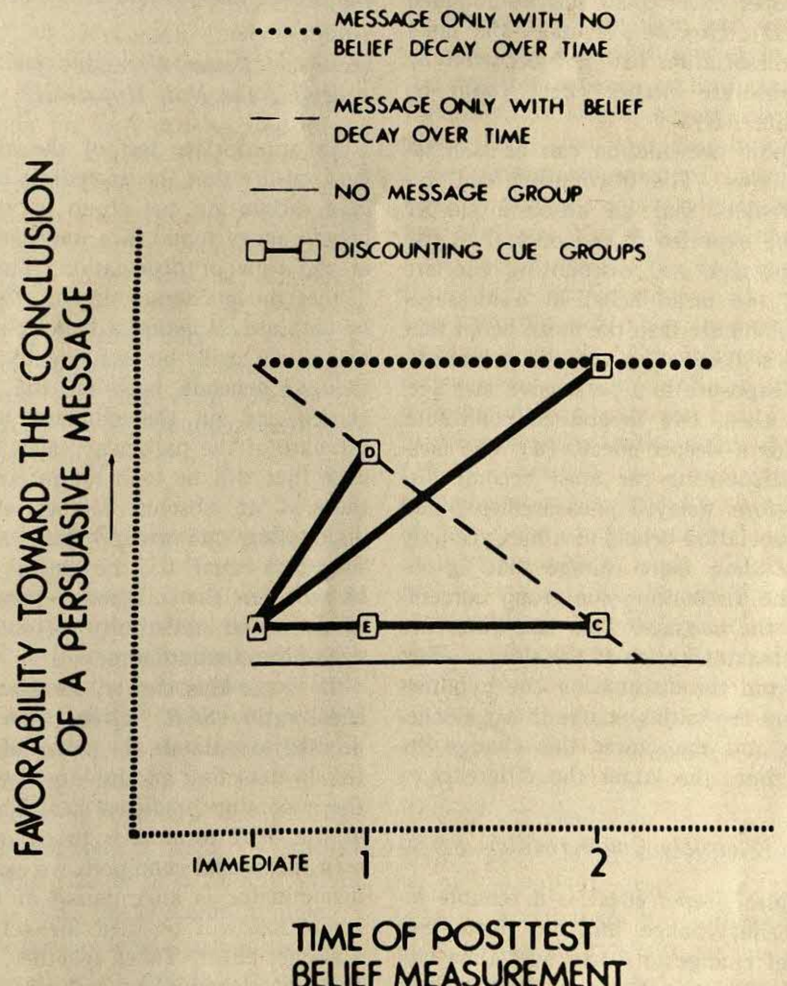

Figure 2. Hypothetical time trends that illustrate that an absolute sleeper effect is a special case of the discounting cue hypothesis.

cue condition will increase to the level found in the message-only condition at the time of measurement. As line *AB* shows, an absolute sleeper effect would be expected to result under these conditions. Imagine next what would happen if all the conditions were the same except that there was decay of belief change in the message-only condition (the dashed line). Then, no absolute sleeper effect would be expected to occur (see line *AC*), though everything else was the same as for line *AB*.

Consider next what would happen if beliefs in the message-only condition were decaying (the dashed line) and dissociation had taken place by Posttest 1 (delayed). An absolute sleeper effect could still be obtained (see line *AD*). However, if under the same conditions dissociation had not occurred by then, no absolute sleeper effect could be found (see line *AE*).

This graphic presentation can be summarized as follows: The discounting cue hypothesis predicts that an absolute sleeper effect can be expected if and only if at the time the message and discounting cue are dissociated, the mean belief in a message-only group is higher than the mean belief that is found in a discounting cue group immediately after exposure to a persuasive message. There are, then, two theoretical conditions necessary for a sleeper effect: (a) The message and discounting cue must become dissociated before delayed measurement, and (b) postdissociation beliefs in a message-only group must show more change than is obtained in the discounting cue group immediately after the message. This last difference defines the maximum size of the sleeper effect predicted from the discounting cue hypothesis; the more the initial change in a message-only group and the slower this change decays with time, the larger the difference.

Ruling Out Plausible Countervailing Forces

An absolute sleeper effect is a reliable increase in belief change, and any force that causes belief change to decay over time will countervail against such an effect. It is commonplace in persuasion research to note that experimentally induced belief changes decay with time. In their review of 30 years of relevant research, Cook and Flay (1978) concluded that despite particular instances of total persistence or sleeper effects attributable to forces other than the discounting cue hypothesis, decay of initial change was the modal finding. Therefore, it is important in designing adequate tests of the sleeper effect to ensure that decay forces of all kinds are minimized. The countervailing power of belief decay is minimal in experiments in which the discounting cue suppresses all of the belief change a message would otherwise have caused. However, such suppression cannot be due to chance, for if it were, statistical regression would result and would masquerade as a sleeper effect.

Statistical Power Necessary for Accepting the Null Hypothesis

An appropriate test of the sleeper effect must ensure that the immediate belief change in a dicounting cue group is less than the belief change found in a message-only group at the time of dissociation. This difference defines the maximum size of effect that can be obtained. Whether a belief change of this magnitude will be statistically significant, though, depends both on the alpha level chosen and on the standard error of the estimate of the particular mean belief difference that will be used for inferring whether there is an absolute sleeper effect in the discounting cue group. Once alpha is assumed to equal .05, the crucial determinant of whether the maximum possible sleeper effect can be statistically corroborated is the size of the standard error.

To make this clearer, consider the sleeper effect ratio (*SER*), given below, which can be used to estimate the power of a statistical test in detecting an absolute sleeper effect of the maximum predicted size. The numerator of the *SER* formula is based on the necessary theoretical conditions we explicated. The denominator is an estimate of the standard error that will be used for actually testing a sleeper effect. Taken together, the numerator and denominator indicate whether the theoretically specified maximum distance over which belief can increase over time in

a discounting cue group is large enough so that if a sleeper effect were to be obtained it could be statistically corroborated. The minimal requirement for an adequate test of the sleeper effect is that *SER* exceed the *t* value associated with the alpha level and the degrees of freedom that are to be used in direct tests of the absolute sleeper effect. The formula is as follows:

$$SER = \frac{M_{\mathrm{PD \cdot MO}} - M_{\mathrm{IMM \cdot DC}}}{\text{Particular standard error used for directly testing the absolute sleeper effect}},$$

where $M_{\mathrm{PD \cdot MO}}$ is the belief mean at the post-dissociation testing (PD) in a message-only group (MO), and $M_{\mathrm{IMM \cdot DC}}$ is the belief mean at the immediate postmessage testing (IMM) in a discounting cue group (DC).

The formula for *SER* can be used in any study to inquire whether the theoretically specified necessary conditions for an adequate test of the sleeper effect are met and whether a statistical test powerful enough to detect the effect, if it exists, can be conducted. However, in practice *SER* can somewhat overestimate or underestimate the power of the subsequent test of the absolute sleeper effect, because sampling error makes the sample means in the *SER* numerator deviate from their population values.

Valid Manipulation and Measurement

Of all the necessary conditions for an adequate test of a phenomenon, perhaps the most obvious is that it must be shown that the manipulation of the independent variable was effective and that the dependent variable was validly measured. In the context of the discounting cue hypothesis, this amounts to finding differences in immediate belief change across groups that were or were not exposed to a discounting cue. Such a finding would illustrate (a) that the discounting cue is effective in reducing belief change and (b) that a measure of belief with face validity is at least reliable enough to discriminate between group means.

Did Past Tests Meet the Logical Requirements for an Adequate Test of the Sleeper Effect?

Was the Countervailing Decay Force Ruled Out?

An adequate test of the sleeper effect requires that there be no immediate belief change in the discounting cue group. The third column of Table 2 shows that immediate belief change occurred in all but three of the experiments in which the relevant differences could be tested. Thus, in most past experiments a decay force may have been set up in the discounting cue group that may have countervailed against obtaining an absolute sleeper effect and may have led to less than adequate tests of it.

Does the evidence confirm our contention that absolute sleeper effects are more likely when there is no immediate belief change in a discounting cue group? To answer this, we need to contrast the results in which there was and was not immediate change. Hovland and Weiss (1951) had two messages that caused immediate attitude change and two that did not. Over 4 weeks, the percentage of subjects with promessage attitudes increased by 30% and 27% for the messages without initial change and by 13% and 3% for the messages with initial change. Falk (1970) obtained no immediate attitude change, and in comparison with other studies, he found one of the strongest indications of an absolute sleeper effect, albeit nonsignificant ($t = 1.50$). Finally, Wilson and Miller (1968) found no initial belief change in the eight conditions in which prosecution arguments preceded defense ones, but found initial change in the eight other conditions in which the order of arguments was reversed. There were some trends in the sleeper effect direction in conditions in which there was no immediate belief change, and there were no indications of sleeper effects in conditions in which there was immediate change.

Ex post facto evidence of this kind is by no means definitive, but it is consistent with our suggestion that absolute sleeper effects are more likely when no immediate belief

Table 2
Extent to Which Requirements for a Strong Test of the Absolute Sleeper Effect Were Met in Past Experiments

				Proxies of the extent to which dissociation of the message and cue took place		
Study	Condition	Was there initial change in discounting cue condition?	Were the requirements of the *SER* formula met?	Percentage recalling cue	Final delay period (in weeks)	Did discounting cue mean differ from others at delayed test?
Hovland & Weiss (1951)	Some messages	Yes	No	55–77	4	No
	Other messages	No	No		4	No
Kelman & Hovland (1953)		DK	No	DK	3	No
Kelman (1958)		DK	DK	DK	1.5	DK
Watts & McGuire (1964)	1–2 weeks	Yes	Yes	36	1–2	Yes
	6 weeks	Yes	No	10	6	No
Johnson, Torcivia, & Poprick (1968)		Yes	Yes	DK	1	Yes
Whittaker & Meade (1968)		Yes	No	DK	4	No
Falk (1970)		No	No	DK	3.9	No
Schulman & Worrall (1970)		Yes	No	8	3.7	No
Johnson & Watkins (1971)	Message 1 time	Yes	No	DK	4	No
	Message 5 times	Yes	Yes	DK	4	Yes
Weber (Note 1)		Yes	No	DK	4	No
Weber (1972)	3 weeks	Yes	Yes	2[a]	3	Yes
	7 weeks	Yes	No		7	No
Gillig & Greenwald (1974)		Yes	Yes	DK	2	Yes
Weiss (1953)		Yes	No	6	6	No
Papageorgis (1963)	2 weeks	Yes	Yes	"Low" recall[b]	2	Yes
	6 weeks	Yes	No		6	Yes
Wilson & Miller (1968)	Prosecution–defense order	No	DK	DK	1	DK
	Defense–prosecution order	Yes				
Holt & Watts (1973)		DK	Yes	DK	1	No

Note. SER = sleeper effect ratio. DK = do not know—cannot be computed from available data.
[a] This figure may not be a true index inasmuch as the data were gathered in an entirely different context from the session in which the source was introduced. The experimenter, setting, and ostensible purpose of the delayed session were intentionally divorced from the first session to minimize the effects of memory and associative cues.
[b] Based on one of the two experimental messages only where an average of .25 qualifiers were recognized out of a total of 2. Chance responding would give .50 correct.

change occurs in a discounting cue condition than when it does.

Were the Necessary Theoretical Conditions Met in Tests With Sufficient Statistical Power?

In its numerator, the *SER* formula incorporates the necessary theoretical condition that the impact of the message at the time of dissociation be greater than the immediate impact of the message when it is linked to a discounting cue. Via its denominator, the *SER* formula probes whether in a particular experiment, sufficient statistical power exists to obtain a sleeper effect of the maximal predicted value. Theoretically, *SER* can be applied to past studies to determine the extent to which each constituted a powerful test of the absolute sleeper effect. In practice, *SER* is not as useful as it could be, since it presupposes the measurement of dissociation, and measures of dissociation are rare in past studies. Moreover, where available, they are invariably associated with single measures that have particular biases. For instance, Watts and McGuire (1964) measured subjects' recognition of the source's name, which presumably overestimates both recall and association. As another example, Schulman and Worrall (1970) had subjects free associate to the message topic, a procedure that may underestimate association, since some subjects may think it inappropriate to mention a source when asked to free associate to a topic. Although it is much better to have such measures than to be without them, they are not by themselves particularly good indicators of message–cue dissociation.

The lack of data on dissociation in past studies forced us to estimate a modified form of *SER*. Since we did not know when dissociation reached acceptable levels, we computed a separate *SER* value for each time interval at which belief measurement took place. Hence, for each study, there were as many *SER* values as delay intervals. To aid interpretation we assumed that dissociation is positively related to the length of the delay interval and is approximately indexed by the percentage of subjects who do not report recognizing or spontaneously recalling a discounting cue.

For only seven studies did the modified *SER* values we computed exceed the t value associated with the statistical test of the absolute sleeper effect, and this occurred in only some experimental groups: (a) in the low-credibility group of Watts and McGuire (1964) after 1 and 2 weeks but not after 6; (b) in Johnson et al. (1968); (c) in the low-credibility–message-five-times condition of Johnson and Watkins (1971), but not in the condition in which the message was presented once; (d) in the experiments of Gillig and Greenwald (1974); (e) in the 3-week-delay condition of Weber (1972) in which the source was mentioned twice, but not in the 7-week-delay condition; (f) in the 2- and 14-day-delay conditions, but not the 41-day-delay condition, of Papageorgis (1963); and (g) for the minor conclusion measure of Holt and Watts (1973).

Two points are worth noting about these experiments. First, immediate belief change occurred in all the discounting cue groups, with the only possible exception being Holt and Watts, in whose study the relevant test of immediate change could not be conducted. Consequently, there are no experiments in which there was both an absence of initial change and a modified *SER* value greater than the t value associated with the statistical test of an absolute sleeper effect. Second, the data suggest that little dissociation may have occurred in studies with higher modified *SER* values. Consider the last three columns of Table 2. Of Watts and McGuire's (1964) subjects, 36% still recognized the low-credibility source after 1 and 2 weeks. Johnson et al. (1968) and Holt and Watts (1973) had a final delay period of only 1 week, and Gillig and Greenwald (1974) had a final delay of only 2 weeks. The typical decay of belief change did not occur in the high-credibility–message-five-times conditions of Johnson and Watkins (1971), which suggests that the message and source may not have been dissociated (although other explanations are possible). And the modified *SER* values in Weber (1972) and Papageorgis (1963) were only large enough with the shorter delay intervals (i.e., at 3 weeks but

not 7 for Weber and at 2 weeks but not 6 for Papageorgis).

The evidence we have just reviewed about dissociation and *SER* values is at best suggestive, but it does imply that high levels of dissociation may not have been obtained in most past experiments in which the modified *SER* value was large enough for a powerful statistical test. More important, it should be noted that all of the experiments with high *SER* values were characterized by immediate belief change in the discounting cue condition. Since a strong test of the sleeper effect requires both the absence of initial change in the discounting cue group and a large enough *SER* value, it is not clear whether the absence of past convincing demonstrations of the sleeper effect was due to the unreliability of the phenomenon or to weak tests of it.

Do Adequate Tests Detect the Sleeper Effect?

Reasons to Suspect That They Do

The results prior to 1978 of tests of the absolute sleeper predicted from the discounting cue hypothesis are ambiguous because one could conclude from them either that there is no absolute sleeper effect or that the tests of it were inadequate. There are two major reasons for suspecting that the latter is true and that the effect might be found if appropriately tested. First, our review of past studies shows that past failures to obtain a sleeper effect occurred in studies in which it is unlikely (a) that all of the theoretically relevant conditions for a strong test were met and (b) that the countervailing force was ruled out. Moreover, ex post facto analyses suggested that the less the initial belief change in the discounting cue group, the stronger the trends toward a sleeper effect.

Second, the dissociative cue hypothesis, the basic theory from which the sleeper effect is derived, was twice directly tested, and each time was corroborated. The dissociative cue hypothesis proposes that both message-acceptance and message-rejection cues can be dissociated from a message over time and that this dissociation eliminates the impact that the cues initially have on belief. Thus, the dissociative cue hypothesis predicts that when a message-acceptance cue is dissociated the decay of change will be accelerated but that when a message-discounting cue is dissociated the initial inhibition of belief change will be eliminated and an absolute sleeper effect will sometimes result. In this sense, the dissociative cue hypothesis is a more general statement of the discounting cue hypothesis we have examined in this article.

Direct tests of the dissociative cue hypothesis have varied the degree of message–source association. Kelman and Hovland (1953) did this when the original message source (of high or low credibility) was or was not reinstated at the delayed measurement session. As predicted from the dissociative cue hypothesis, (a) in high-credibility conditions, attitude decayed less when the source was reinstated than when it was not, and (b) in low-credibility conditions, belief showed a trend toward a sleeper effect when the source was not reinstated and no such trend when it was. In a related experiment, Weber (1972) manipulated the strength of the message–cue association during exposure to the persuasive message rather than by reinstating the source at the delayed measurement. Weber had subjects learn about a high- or low-credibility communicator whose name was mentioned twice (low association) or 22 times (high association) in the course of reading and then rereading a long persuasive message. Belief was assessed immediately after the message for all subjects, and 3 weeks later for some of them and 7 weeks later for the remainder. The delayed assessments were conducted in subjects' living quarters by experimenters who did not know the hypothesis, and it is likely that the earlier experiment was not reinstated. Weber's time trends (see Figure 3) are very similar to those of Kelman and Hovland, and the overall three-way interaction of credibility, strength of association, and time of measurement was statistically significant at the 5% level (one-tailed test). It seems, then, that the basic dissociative cue hypothesis is correct. This hypothesis buttresses the prediction of a sleeper effect,

which suggests—but does not prove—that such an effect would be obtained if a strong test were conducted.

Results of Adequate Tests of the Sleeper Effect

When demonstraby adequate tests of the absolute sleeper effect were conducted, they repeatedly resulted in absolute sleeper effects (Gruder et al., 1978). In one experiment subjects read a persuasive message about either the disadvantages of a 4-day work week or the disadvantages of permitting right turns when traffic lights are red. Each message was or was not accompanied by a brief statement that suggested that the information in the message was false. Subjects' beliefs were assessed both immediately after the message and 5 weeks later at an unrelated experimental session. The data showed (a) that the discounting cue manipulation suppressed all belief change for the 4-day work week topic but not for the right turn on red topic and (b) that *SER* was large enough for the 4-day work week topic but not for the right turn on red topic. Thus, the requirements for an adequate test of the absolute sleeper effect were clearly met for one message and not for the other. Analysis of the belief data showed a statistically significant sleeper effect for the message in which the requirements were met but no such effect for the message in which they were not met.

A second experiment was designed to replicate and extend the first by linking the 4-day work week message to five different discounting cues that varied in strength and kind. Half the subjects' beliefs were measured immediately after the message, and all the subjects' beliefs were measured by phone 6 weeks later by persons who did not know the subjects' experimental conditions. Analyses of the data relevant to the requirements for an adequate test showed that (a) there was no immediate attitude change in three of the five discounting cue groups; (b) *SER* was large enough for these three groups; and (c) direct measures of dissociation revealed that over 75% of the subjects in each cue group dissociated or forgot the cue. Thus, the requirements for an adequate test were clearly met for three cue groups, but were not met for the other two. Absolute sleeper effects were reliably obtained in the three cue groups in which the requirements were met and not in the two cue groups in which the requirements were not met.

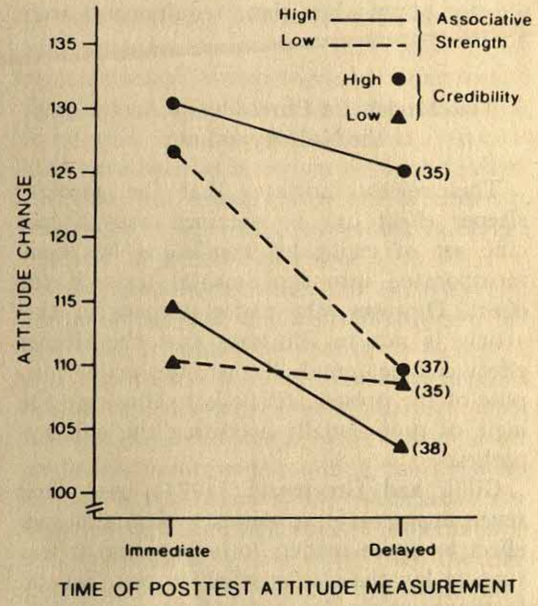

Figure 3. Persistence of attitude change as a function of source credibility and source–content associative strength in Weber (1972), whose relevant data are reproduced with his permission. (Sample sizes are in parentheses, and the 3- and 7-week-delay groups are collapsed because there were no theoretically meaningful effects of the length of the delay period.)

These studies demonstrate that the absolute sleeper effect that is predicted from the discounting cue hypothesis is both reliable and valid. It is reliable in the sense that it has been replicated across experiments, discounting cues within experiments, repeated versus not repeated belief measurements, and two different techniques of delayed measurement. Though replication with different messages and in different laboratories is still needed, it does seem that the absolute sleeper effect is valid by criteria of both convergent and divergent validity insofar as the effect occurred when the logical requirements for an adequate test were demonstrably met and

did not occur when these requirements were not met.

Two Models for Provisionally Accepting the Null Hypothesis

This review indicates that the absolute sleeper effect can be obtained once a specific set of explicated conditions has been incorporated into experimental tests of the effect. However, the major purpose of this article is not to illustrate that the sleeper effect can be found. Rather, the major purpose of the present article is to illustrate the logic of provisionally accepting the null hypothesis.

Gillig and Greenwald (1974) used their seven unsuccessful attempts to find a sleeper effect to invite readers to believe that it was time to lay the sleeper effect to rest. Several textbook writers have already accepted their invitation, despite the fact that it may well be based on an implicit inductive fallacy: The more numerous the failures to obtain an effect, the less likely it is to exist. In a later article, Greenwald (1975) used the so-called nonexistence of sleeper effects as a major illustration of the factors that indicate "How to Accept the Null Hypothesis Gracefully" (p. 16). These factors are as follows:

1. "Use a range, rather than a point, null hypothesis" (p. 16).
2. "Select N on the basis of a desirable error of estimate of the test statistic" (p. 16).
3. "Have convincing evidence that manipulations and measures are valid" (p. 17).
4. "Compute the posterior probability of the null (range) hypothesis" (p. 17). (Doing this led Greenwald to conclude from his own studies of the sleeper effect that the posterior odds ratio in favor of the null hypothesis is 1:249 as opposed to 1:19 for $\alpha = .05$.)
5. "Report all results of research for which conditions appropriate to testing a given hypothesis have been established" (p. 18). (Greenwald elaborated on this by stressing the Type I errors that result from the nonpublication of nonsignificant findings.)

With the exception of Point 3, Greenwald's list is statistical, and the casual reader might infer from this and from Gillig and Greenwald that acceptance of the null hypothesis is largely a matter of the statistical power of a study or a set of related studies and that the more past failures to obtain the effect in question, the higher should be the confidence in accepting the null hypothesis. Although this perspective on the null hypothesis is useful, it must be incomplete, since it led to incorrect acceptance of the null hypothesis about the sleeper effect. What is incomplete about this perspective?

First, it does not stress the importance of deducing from the parent theory (the discounting cue hypothesis in the sleeper effect case) the theoretical conditions that are necessary for a particular effect. Explication of the discounting cue hypothesis makes it clear that the effect should only be predicted when the belief found in a discounting cue group immediately after a message is at a lower level than the belief found in a message-only group just after dissociation. Given that the parent theory specifies the conditions under which a sleeper effect should be obtained, it is incumbent on any researcher to ensure that these conditions are met in experimental tests. If the conditions are not met, it does not matter how many tests are conducted, because they will all be inadequate.

Second, it is important to use background theory and common sense to specify extraneous forces that might plausibly countervail against the phenomenon under investigation. In the sleeper effect case, one very plausible countervailing force is the decay of belief change. Such decay is regularly found after belief change has been obtained as a consequence of an effective persuasive message. Of course, belief does not invariably decay, and it is logically impossible to specify all the potential suppressor variables. But despite such complications, researchers who want to provisionally accept the null hypothesis need to show that countervailing forces have not operated in studies to mask the effect under investigation.

Third, statistical considerations are crucial if one wants to act as though the null hypothesis were true. This is clearly recognized

in Greenwald's (1975) perspective, which urges researchers to design experiments so that the standard error of estimate of the test statistic is desirable. However, how should one define what is desirable? Fortunately, there are some cases in which theory allows one to specify a numerical value for the desirable standard error. In the sleeper effect case, the maximum possible size of the effect can be specified by subtracting the difference between the immediate posttest belief mean in a discounting cue group from the postdissociation belief mean in a message-only group. Then one can easily solve for the size of the standard error that is necessary for an adequate test of the sleeper effect. (The *SER* formula incorporates all of the factors necessary for the computation in question.) There are, of course, many situations in which the underlying theory is not so precise and in which the practicing researcher does not have independent knowledge of the maximum magnitude of the effect. In such situations, one might well follow Greenwald's advice and keep the standard error low by using range estimates of the effect instead of points. But where the theory specifies the magnitude of an expected effect, the size of the necessary standard error can be computed.

On another issue our perspective entirely overlaps with Greenwald's, for accepting the null hypothesis depends on demonstrating that the manipulations and measures are valid.

The essence of the difference between the two perspectives is that Greenwald's stresses statistical concerns pertinent to evaluating no-difference results from a single study or a set of highly similar studies, whereas our perspective stresses the logic of using theory prior to data collection to deduce the conditions that are necessary for an effect and to deduce any conditions that might countervail against the effect. Unless these conditions are explicated and demonstrably incorporated into the research, statistical criteria matter little, and the number of failures to obtain a given effect is uninformative. Our stress, then, is (a) on the logic of explicating the necessary theoretical, countervailing, statistical, and procedural conditions for an effect; (b) on deducing which research operations will represent these conditions; and (c) on demonstrating via appropriate measurement that all of these conditions have been incorporated into the experimental tests. If they have been so incorporated but the effect still does not appear, then one is closer to being able to act with justification as though the null hypothesis were true.

Other factors, although not necessary for adequate tests of the null hypothesis, are desirable. It would be foolish to accept a null hypothesis if some secondary implication of this acceptance were patently false. For instance, the sleeper effect is a single prediction from the discounting cue hypothesis that is itself part of the dissociative cue hypothesis. Since independent experimental tests have strongly suggested that the dissociative and discounting cue hypotheses may well be correct (Kelman & Hovland, 1953; Weber, 1972), this alone should give one reason to pause before using no-difference findings to claim that the sleeper effect should be laid to rest.

When accepting the null hypothesis, there is sometimes value in replication. Cronbach and Snow (1977) have correctly pointed out that if many unbiased studies show nonsignificant effects in the same direction, then the null hypothesis can be rejected. (The stress here has to be on *unbiased,* for multiple biased tests provide no information if the bias operates in the same direction across all the studies.) By the same token, acceptance of the null hypothesis is facilitated if in many studies in which the necessary logical conditions for an effect have been met, the effect does not appear and there is no pattern to the nonsignificant results.

Other advantages of replication emerge in considering the question, Are there any circumstances under which one could incorporate all the necessary theoretical, countervailing, statistical, and procedural requirements into an experiment but still fail to find a true effect? Obviously, chance dictates that a Type II error can occur, and replication is the way to examine this threat. A less obvious circumstance in which one might falsely conclude in favor of the null hypothesis is one in which all the known necessary condi-

tions for an effect are met but unknown necessary conditions are not. Imagine that absolute sleeper effects can occur under the conditions we have specified, but only if the discounting cue follows the persuasive message. In this case, experimental tests that met all the derived necessary conditions but presented the discounting cue before the message would lead to a false acceptance of the null hypothesis. The practical difficulty with such unknown conditions is that they cannot be deliberately incorporated into the research. Consequently, it is advantageous to postpone acting as though the null hypothesis were true until a number of studies have been conducted that meet all the necessary conditions derived from the theory and also vary a number of factors that might plausibly be additional necessary conditions.

Since one can never know in practice whether one has met the true necessary (and sufficient) conditions for any effect, inferences about the null hypothesis must inevitably and logically be imperfect and subject to later correction. As Cook and Campbell (1979) have pointed out in their extended discussion of the null hypothesis, inferences in favor of the null hypothesis should be thought of as decisions to act as though this hypothesis were true and not as knowledge that the hypothesis is true.

Human Crowding and Personal Control: An Integration of the Research

Donald E. Schmidt and John P. Keating
University of Washington

Empirical and theoretical discussions have suggested that crowding is experienced when situational density forces the blocking of goals, the interruption of behaviors, or cognitive overload to occur. However, no psychological principles have been employed to unify these explanations. The present article attempts to link the literature on human crowding with the experimental research on personal control. Averill's distinctions among behavioral, cognitive, and decisional control are discussed in the context of human crowding. A conceptual model is offered that suggests that crowding is an attributional label applied to a setting when situational density results in a loss or lack of personal control.

The development of industrialization in the United States has been associated with a shift from a dispersed, agriculturally based society to a relatively centralized urban culture and a period of rapid population growth (Davis, 1965; Meadows, Meadows, Randers, & Behrens, 1972). These general population growth patterns have created dense urban environments in which the majority of the population resides (Hawley, 1971). Perhaps this is why human crowding has become a central topic of research in the emerging subdiscipline of environmental psychology.

Theoretical discussions of crowding have focused on two overriding questions: What physical, social, and personal factors determine an individual's experience of crowding, and what are the psychological and physiological consequences of being crowded on a long-term basis? Although the literature has grown to voluminous proportions, it does not yet offer definitive answers to these questions (Lawrence, 1974).

Initial animal studies established relationships between population density and psychosocial and physiological anomalies. Calhoun (1962) created rat colony densities that were well above levels previously associated with stress. Under these conditions, he found a variety of abnormal developments, including the disturbance of normal maternal behaviors, cannibalism, homosexuality, and the disruption of a number of physiological processes. Christian, Flyger, and Davis (1960) observed the density-related mass mortality of a herd of silka deer on a small island off the Maryland coast. Autopsies of the deer carcasses revealed no consistent evidence of disease or malnutrition, but the presence of enlarged adrenal glands was an apparent sign of stress (cf. Selye, 1956). Results similar to those observed by Calhoun and Christian et al. have also been found in house mice (Southwick, 1955), lemmings (Clough, 1965), and snowshoe hare (Deevey, 1960). Although it is unclear what specific factors contributed to these effects, a plausible explanation has been offered by Christian (1963). He postulated that high levels of population density may have created intraspecies competition for available space and resources. The psychological pressures (stress) that resulted

Preparation of this manuscript was supported in part by University of Washington Graduate School Research Fund Grant RR-07097.

We would like to extend special thanks to Lee Beach, Andrew Davidson, Nickolaus Feimer, and Robert Sasanoff for reviewing initial drafts of this article and to Robert Bolles for his help on references to the animal literature.

may have culminated in the observed maladies.

Subsequent demographic–correlational studies have attempted to relate these findings to human populations. Associations between population density and indices of crime, disease, and the like commonly have been found (e.g., Galle, Grove, & McPherson, 1972; Hawley, 1972; Schmitt, 1966). However, as provocative as the animal studies and correlational analyses appear, their applicability to conditions encountered in large urban settings is severely restricted. Correlational analyses using relatively gross demographic indices provide only general information about these associations and do not answer questions concerning causation. Similarly, generalization of the results from animal studies to human populations in cities is tenuous. Stages of phylogenetic development have clearly increased the ability of humans to deal with and adapt to conditions in the external environment (Glass & Singer, 1972; Schneirla, 1971; Stokols, 1972b). Thus, the response of other species of animals to external conditions may be noticeably different from that of humankind.

For humans, the relationship between population density and an individual's perception of crowding is far from perfect. Stokols (1972a) has made a useful distinction between these two measures. Population density is defined as a measure of the number of people per unit area, which is strictly a physical index. Alternately, Rapoport (1975) has described functional density as a measure of the number of others within a setting who directly affect an individual's behaviors and perceptions. This extension of the concept specifies a subjective determination of the physical concept. Crowding, on the other hand, is a cognitive evaluation that is predicated on the individual's negative affective reaction to the immediate environment. Stokols (1972a) noted that although density is a necessary antecedent of the perception of crowding, it is not a sufficient cause. Situational constraints, as well as personal and social factors, are also important determinants of this negative evaluation of the environment (Altman, 1975; Carr, 1967; Hall, 1966; Schmidt, in press). Hence, although density must be present for the evaluation to be made, social and dispositional influences also play an important role in the judgment of crowding.

The two primary theoretical approaches developed to explain the crowding response are the behavioral constraint or social interference model and the cognitive overload position. Both approaches incorporate physical, social, and dispositional factors. These explanations have helped to clarify the relationship between density and crowding, since they specify a number of environmental conditions, produced by situational density, that result in an evaluation of crowding. It is important to make clear from the outset of this discussion that some nonspecific level of density is always assumed to be necessary for the production of behavioral constraint, social interference, or cognitive overload. Crowding is expected to result only when the antecedent level of density is present. Second, crowding is treated as the result of the physical consequences of density in these explanations and not as any specific social process resulting merely from the interacting presence of others. A situation is evaluated as crowded when the presence of others results in interference and not when interference is produced only by social interactions with others; that is, crowding has been treated as a physically based and not a socially based reaction to the environment; it is not interference per se but interference related to density that results in an evaluation of crowding.

Behavioral Constraint/Social Interference Explanation

The behavioral constraint or social interference explanation posits that a situation will be evaluated as crowded when density or other related conditions restrict or interfere with the activities of an individual within the setting. This approach is modeled after the theory of psychological reactance, in which Brehm (1966) stated that maintenance of freedom of choice is an important motivating factor in human behavior and perception. He argued that people are disposed to maintain or restore freedom when it

is threatened and that an individual's reaction to a setting is dependent on his or her success at accomplishing this goal. Proshansky, Ittelson, and Rivlin (1970) have discussed reactance in relation to environmental perception. They noted that crowding is experienced when situational density leads to a frustration of an individual's pursuit of important activities and goals. This frustration may be the result of actual physical interference or of the mere presence of others, both of which are construed as limitations of behavioral choices (Stokols, 1972b; Stokols, Rall, Pinner, & Schopler, 1973).

This perspective of limited freedom has been adapted in several theories of crowding. Altman (1975) described social behavior in terms of a privacy-control mechanism that attempts to regulate the frequency of social contacts. According to Altman's model, crowding occurs when the amount of actual social contact exceeds the level that is desired. The person is unable to effectively limit interactions with others. Similarly, Esser (1973) viewed crowding as the result of "not having one's way." This occurs when the denseness of people in a setting creates social interference and hence prevents an individual from functioning effectively. Saegert (1973) noted that high-density environments may create social interference, competition for scarce resources, and the restriction of behaviors that increase perceived crowding. Finally, Stokols (1972b) postulated that an individual experiences crowding when the demand for space required by a specific activity exceeds the available supply.

The research investigating this explanation of crowding has generally provided confirmatory results. Sherrod (1974) conducted an experiment in which three density conditions were manipulated: low density, high density, and high density with control. In the first two conditions, subjects were placed in either dense or nondense settings, but were not given the option of leaving the room. In the third condition, subjects could freely choose to leave the setting. Sherrod found that subjects displayed more decrement in performance on a complex cognitive task and less persistence on an unsolvable puzzle administered subsequent to interaction in a high-density setting relative to a low-density setting. However, perceived control in the high-density setting appeared to ameliorate these negative aftereffects. It is important to note that subjects never actually exercised the option to leave the setting, and hence it was perceived rather than actual control that contributed to these effects.

Sundstrom (1975) manipulated room size and goal blocking independently in an experimental setting. In this study, goal blocking was operationalized as interruption or inattention by others. Subjects reported greater irritation, which increased over time, when goals were blocked than when they were not. However, the amount of self-reported irritation was unrelated to the level of room density. Sundstrom noted that high-density conditions may cause disruption of interpersonal interactions, which subsequently produces psychological stress. On the other hand, density should be unrelated to stress when the number of people present in a setting does not functionally interfere with goal-directed behaviors. Stokols et al. (1973) found that subjects felt more crowded in competitive as compared with cooperative groups, suggesting that the number of people present in a competitive situation may be more salient because they either actively or potentially inhibit the individual from attaining a desired goal or outcome. Hence, the individual is more likely to evaluate the situation in a negative way. Wicker, Kirmeyer, Hanson, Alexander (1976) found that subjects evaluated an experimental setting as more crowded when there were not enough people to perform all of the required tasks, an "undermanned" situation. Perceived crowding was significantly less in the "overmanned" condition, a relatively higher density setting. Since assignments in the undermanned condition required considerable physical movement, often leading to behavioral interference among subjects, this result is supportive of the freedom and control hypothesis. Density is related to crowding when it is expected to reduce the individual's control over the environment. Crowding does not occur when density does not affect behavior or goals.

Schmidt, Goldman, and Feimer (1979) conducted a large-scale field study measuring evaluation of crowding at the residential, neighborhood, and city levels and related these variables to a number of psychological and physical measures. They found that psychological measures indicating some degree of control (e.g., privacy) over the environment were associated with perceived crowding at all levels of the analysis (cf. Altman, 1975; Johnson, 1974). Further, psychological variables became increasingly important and physical measures decreasingly important as one moved from the more immediate residential setting to the less immediate neighborhood and city settings. Schmidt et al. suggested that in the residential setting physical density had a direct effect on the residents' behaviors and activities. However, at the neighborhood and city levels of analysis, crowding evaluations were less tied to objective levels of density and more closely aligned with the impact of more general urban conditions on an individual's behaviors and activities.

Norms, Control, and Crowding

Previous theoretical statements that have been presented concerning the relationship between crowding and perceived freedom and control suggest that normative standards and expectations may have an important effect on evaluations of the environment (Proshansky et al., 1970; Schmidt, in press; Stokols, 1972b; Stokols et al., 1973). Personal control and the subsequent perception of crowding involve individual assessments that are based on the person's expectations. Since norms specify common behavioral standards, they provide predictability that increases control in a social situation (cf. Lefcourt, 1972). While norms increase situational control, violation of such norms decreases control. From this perspective, density leads to an evaluation of crowding when it violates situationally appropriate social or spatial norms. However, the existence of different behavioral and spatial norms among various social subgroups and cultures provides an interesting degree of complexity, a point made especially clear in the anthropological literature (e.g., Hall, 1966; Watsen & Graves, 1966).

Anderson (1972) suggested that high densities may increase the likelihood of highly charged social interactions that cause stress. He noted, however, that in Chinese cultures, large personal spaces are not intrinsically valued and that the existence of well-established behavioral and spatial standards reduces the potential for stressful social interactions induced by close physical proximity, thus reducing the experience of crowding. Draper (1973) reported that among the !Kung bushmen, a hunter–gatherer tribe of southwestern Africa, extremely high-density living is common and preferred. However, periodic escape into outlying desert areas appears to mitigate the potentially stressful effects of high-density living. Finally, Schmidt, Goldman, and Feimer (1976) found that white, black, and Chicano subcultural groups used distinctly different criteria in evaluation of the environment. Crowding was a subjectively different experience for each of the three groups. Black and Chicano subjects tended to focus on a wider range of urban factors in their judgments concerning crowding than did their white counterparts. The above studies suggest that culturally different evaluative and behavioral standards affect environmental judgments.

Several studies have investigated the violation of situationally specific norms as they are related to the evaluation of crowding. Baxter and Deanovich (1970) instructed confederates to position themselves at an inappropriately close or normal spatial distance from an experimental subject. Compared with subjects in the normal condition, subjects in the inappropriately close condition (normative violation) reported that they felt more crowded and displayed higher projective anxiety in describing figures illustrated in a scenario situation in close physical proximity. Freedman, Levy, Buchanan, and Price (1972) tested males and females in small and large experimental rooms. A statistical interaction between sex of the subject and room density was obtained; women felt less crowded in the small (dense) room than did men. Additionally, women

tended to be more cooperative in the small room, whereas men displayed more competitive behaviors. Epstein and Karlin (1975) found similar results in a study of acute crowding. Males tended to form fragmented, competitive groups in the dense condition, whereas females were more cohesive and cooperative. Epstein and Karlin suggested that these effects may be attributable to differential sex norms. Females are expected to share their distress and therefore form more cohesive groups. Males, on the other hand, are expected to hide distress, which purportedly leads to a more fragmented group orientation. Leibman (1969) also has suggested that socialization of sex roles may be associated with different personal-space requirements for men and women. Different criteria may be applied by the sexes when each evaluates a setting and makes a judgment of crowding.

Locus of Control and Crowding

Although most research has been concerned primarily with situational control, certain dispositional characteristics affecting perceived personal control have also been related to the perception of crowding. Research investigating the locus-of-control personality construct (Rotter, 1966) has found differences in reactions to density and in personal-space needs. In an experimental group situation Schopler and Walton (Note 1) found that subjects classified as internals felt less crowded than subjects classified as externals. Similarly, Duke and Nowicki (1972) found that externals had larger personal spaces than internals on a pencil-and-paper measure in which subjects were asked to imagine the approach of a fictitious stranger and to estimate at what distance they would begin to feel uncomfortable. Personal-space distances are thought to act as buffers between the individual and social contacts, hence offering the individual some control over the quality and nature of interpersonal interactions (Hall, 1962, 1966; Sommer, 1969). In the context of the behavioral constraint explanation of crowding, internals presumably have a greater tolerance for interference from the environment, since they perceive a greater degree of personal control over it. Externals, on the other hand, may perceive generally less control over these conditions and consequently may require larger buffer zones. Similarly, less interference from the environment elicits negative evaluations of crowding.

In summary, the theoretical definition of crowding considered above postulates that an environment produces negative affect and is evaluated as crowded when social or physical factors reduce the amount of perceived freedom and control. Increased levels of density create conditions that make it difficult for the individual to function effectively in a setting by blocking goals and interfering with organized behavioral sequences. Since norms set behavioral standards and expectancies that structure social situations, they increase predictability and personal control over a setting. Similarly, normative violations attributable to density should lead to greater evaluations of crowding, since they functionally reduce situational control. However, because normative standards vary between cultural and social groups, different physical and social conditions may lead to violation of different behavioral and spatial standards according to the particular group considered. Finally, perceived locus of control may differentially affect the criteria that the individual applies to a situation in determining whether control can be maintained and if the situation can be labeled as crowded.

Stimulus Overload Explanation

The stimulus overload formulation predicts that a setting is evaluated as crowded when an individual is overwhelmed by the presence of others or when physical conditions in the environment increase the salience of social density. This is an explanation that relies primarily on interference at a perceptual or cognitive level, in contrast with the behavioral restrictions discussed in the previous section. The stimulus overload conceptions of crowding have been based, for the most part, on early urban sociological theories. Attempting to specify the defining qualities of a city, Wirth (1939) noted that urban areas can be characterized in terms

of their size, their density, and the heterogeneity of the encompassed populations. These characteristics often result in the exposure of city residents to excessive levels of physical and social stimulation. Simmel (1950) suggested that urban dwellers conserve psychic energy by developing proportionally fewer and more superficial interpersonal relationships than do individuals residing in rural areas. Presumably this protects a person from becoming overwhelmed by large numbers of social contacts.

An elaboration of the early sociological papers was presented by Milgram (1970). He noted that the many stimuli that impinge on the individual in urban areas may overwhelm the person's cognitive-processing capabilities. Milgram believed that selective attention to only a small subset of the possible social and physical environmental stimuli is a strategy for dealing with this problem. Hence, individuals spend less time with each social contact and develop more superficial interpersonal relationships with others. Wohlwill (1966) suggested that the investigation of the physical environment is largely a study of stimulation, that optimal amounts must be defined and the concept of adaptation level (Helson, 1947) explored. Lee (1966) noted that individuals learn cognitive strategies that help them avoid or modify incoming stimuli from the environment. Such strategies may allow a person to prevent overstimulation and perceptually to filter out the potentially stressful elements of a setting. The privacy-control mechanism postulated by Altman (1975) is also consistent with a stimulus overload interpretation. Crowding results when a level of social stimulation occurs that is greater than that desired by the individual. However, judgments about what is considered to be the optimal level of social contact may vary from situation to situation.

A number of studies have offered support for this position. Desor (1972) asked subjects to place miniature figurines in a model room until they felt that the room was just short of being crowded. The number of entrances to the room and the presence or absence of partitions were varied. She found that more figurines were placed in rooms when there were partitions present and fewer external entrances. Additionally, the type of activity taking place affected judgments about the appropriate number of people in the room. This result is consistent with Altman's model, since partitions and entrances regulate social contacts and different types of activities are associated with different desired levels of social contact. Valins and Baum (1974) found that students tended to rate corridor-style dormitories as more crowded than suite-style dormitories. They suggested that the former design is less efficient at shielding residents from unwanted social stimulation. Baum, Reiss, and O'Hara (1974) found that when a confederate was placed in close proximity to the subjects, individuals were less likely to stop and drink from a water fountain if there was not a screening barrier. Presumably these barriers shielded the fountain user from unwanted visual intrusion or the possible violation of personal space.

Saegert, Mackintosh, and West (1975) found that density was most likely to produce psychological effects under three conditions: (a) when an individual was required to scan and interact in a setting, (b) when density was created by increasing the number of people rather than by varying the room size, and (c) when there were a large number of people present in a setting. This suggests that the salience of social density may be an important part of this effect (cf. Loo, 1973; Rapoport, 1975) and that various activities, social conditions, and tasks focus attention on or away from physical density. Saegert (1973) reported that patrons in a Manhattan department store were less able to recall details of the store in high- versus low-density conditions. This finding is explained by Milgram's (1970) proposal that urban dwellers filter out irrelevant stimuli in the environment to prevent cognitive overload created by a complex and active surrounding.

In summary, stimulus overload explanations of crowding have been based on sociological theories that primarily describe the city in terms of size, density, and the cultural heterogeneity of the encompassed populations. These characteristics combine to

overwhelm the urban dweller's perceptual processing of the environment. Urban residents attempt to evoke strategies that help reduce the occurrence of this cognitive overload. These cognitive and behavioral strategies reduce exposure to the source of the overload or reduce the impact of stimulus overload. Crowding, defined in this way, occurs when the person is unable to cope effectively with the perceptual or cognitive interference created by density. An important component of this model is the notion that optimal levels of stimulation are situationally determined by the individual. The perception of crowding is greatest when the level of stimulation incurred is beyond the level desired and the person is unable to effectively eliminate or reduce such overstimulation. The stimulus overload position is primarily concerned with interference and disruption of perceptual or cognitive information processing.

Crowding and Personal Control Over the Environment

The thesis of the present review is that the theoretical explanations of crowding discussed above all describe either a lack or loss of control over the environment. Density-related conditions functionally reduce the individual's ability to maintain situational control. Second, the perception of crowding is an evaluation in response to this lack or loss of control when density is a salient and viable cause of such absence of control. The behavioral constraint/social interference explanation posits that an environment will be rated as crowded when other people in the setting inhibit or block goals and behaviors. Similarly, the stimulus overload conceptualization posits that the perception of crowding is related to the inability of the individual to control the level of social stimulation.

Personal control is not a simple psychological variable. Rather, it is a complex composite of different concepts that are applicable to the present discussion. These components of control noticeably crosscut the theoretical discussions of crowding that were detailed previously. Averill (1973) has distinguished three primary categories of control: behavioral, cognitive, and decisional.

Behavioral Control

Averill (1973) defined behavioral control in terms of two components: regulated administration and stimulus modifiability. Regulated administration specifies who administers the noxious stimuli (i.e., self-administered by the subject or under external control). Stimulus modifiability refers to how and when the stimulus is encountered. In the experimental research on personal control, stimulus modifiability has involved prevention of noxious stimuli, premature termination of the stimulation, or direct modification of the form of the stimulation. Johnson (1974) similarly defined two components of behavioral control: behavioral selection and outcome effectance. Behavioral selection refers to the presence of viable behavioral options that can be selected by the individual. Johnson noted that the more diverse these options appear, the more personal control is perceived (cf. Steiner, 1970). Outcome effectance refers to the link between initiated behaviors and the final attainment of outcomes or goals. Established relationships between specific behaviors and the attainment of various outcomes increase perceived control by structuring the situation and adding predictability (Lefcourt, 1972). In sum, then, behavioral control involves the ability to choose actions that deal effectively with aversive stimuli and to attain desired outcomes. It also involves coping behaviors that deal with aversive qualities of the environment and aid in the successful pursuit of goals in a specific setting.

In the context of the preceding crowding explanations, behavioral control is applicable in a number of ways. First, the behavioral constraint or social interference position deals with a blockage or inhibition of the behavior–goal relationship. This explanation posits that social density often disrupts behaviors or makes certain outcomes unattainable and that this interference leads to the perception of crowding. Mandler (1964) suggested that the interruption of organized behavioral patterns produces arousal that is

evaluated as positive or negative according to the context of the situation (cf. Schachter & Singer, 1962). Interference that inhibits the relationship between behaviors and outcomes is often disruptive, since it blocks situationally appropriate activities. Hence, this arousal may lead to a negative evaluation of the source of the disruption. When density interferes with goal-directed behaviors, a negative affective attribution of crowding may result (Sundstrom, 1975; Wicker et al., 1976). Similarly, density is not related to negative affect when it does not cause the blocking of goals or the inhibition of behaviors.

Research has provided support for this position. Sundstrom (1975) found that self-reported stress and irritation were not related to the level of density when the blockage of behaviors and goals was independent of density. Wicker et al. (1976) found that there was more perceived crowding in a lower density setting as compared with a higher density setting when behavioral interference occurred in the former but not in the latter. Hence, it is apparent that behavioral interference caused by other people in the setting is a critical factor in determining whether the situation will be evaluated as crowded. Crowding only occurs when antecedent density is a source of the disruption.

The ability to exercise direct behavioral control over an aversive stimulus also reduces negative affective responses. Corah and Boffa (1970) found that control over the termination of a stressor (noise) decreased the subjectively rated aversiveness of the stimulus and reduced physiological indices of arousal (see also, Glass et al., 1973). Similarly, Glass and Singer (1972) found that control over the onset, termination, or predictability of noise reduced negative aftereffects on postexperimental tasks. In this series of studies, subjects perceived that they had control over onset or termination of the stimulus, although no actual control was ever exercised. Other studies have shown lower indices of autonomic arousal for subjects with perceived control over aversive stimuli (e.g., shock) as compared with those without control (e.g., Geer, Davison, & Gatchel, 1970; Mahler, 1973; Starke, 1973). Sherrod (1974) performed a partial replication of the Glass and Singer studies using density as the environmental stressor. He found that compared with the condition of no perceived control, perceived control over the experience of density resulted in a smaller decrement in performance on a postexperimental task. Control in this study involved the freedom to leave a dense setting, although actual control was never exercised. Clearly, perceived control reduces both negative perceptions of a stimulus and aftereffects that may result.

In some situations, however, the individual may be unwilling to assume control when it is possible. Rodin (1976) grouped subjects in a laboratory study on the basis of whether they lived in relatively high- or low-density housing. Subjects were run through a series of experimental tasks in which they either failed or succeeded. She found, in general, that children living in dense housing were less willing to modify the operant task in which they were engaged (i.e., to change reinforcement contingencies by pressing a button). The same children were also more likely to fail on a solvable experimental problem if they had experienced initial failure on an unsolvable problem. Rodin suggested that children living in dense housing may learn that controlling one's environment is difficult. This lack of behavioral control was reaffirmed by outcomes on the initial task.

Coping also provides an alternate method for maintaining behavioral control over an aversive stimulus. When the ability to directly modify the stimulus or to determine when it will be encountered is uncertain, the individual may either implement behaviors that reduce the impact of the stressor or choose to avoid it altogether. The stimulus overload literature suggests that withdrawal is an obvious strategy for coping with excessive stimulation from high-density environments. Milgram (1970) proposed that social withdrawal is a response to cognitive overload created by the presence of large numbers of people. Similarly, the behavioral constraint/social interference explanation of crowding recognizes that situational escape and avoidance of social interactions are ways

of reestablishing control that is threatened in a dense setting (Altman, 1975; Schmidt, in press; Stokols, 1972b).

Research that has looked at coping and crowding has defined withdrawal in one of two ways. The first is in terms of passive avoidance of social interactions. Tucker and Friedman (1972) observed naturally occurring groups at three college locations with surrounding city areas that varied in population density. They found an inverse relationship between group size and city density. They suggested that the establishment of fewer interpersonal contacts may be a strategy for dealing with higher levels of density. Loo (1972) studied groups of young children at play. She noted that as density increased, both the number of social interactions and the incidence of aggressive behavior decreased. Further analyzing these data, she found that while there were no significant differences for girls, boys tended to be more aggressive in the low-density conditions. Hutt and Vaisey (1966) observed that groups of normal children at play interact less in high-density situations and more in low density conditions. Sundstrom (1975) observed less self-disclosure in an experimental setting in which density was high. He observed significantly less eye contact, gesturing, and positive head nodding in manipulated goal-blocking conditions than in conditions in which goal blocking did not occur. In this study the observed behavioral (passive) withdrawal was unrelated to room density. Subjects withdrew from interactions in response to goals that were blocked. Again, Sundstrom manipulated goal blocking and density (room size) as independent factors. Hence, these results offer evidence that the subjective impact of density, rather than objective physical conditions, is important in determining which environmental factors lead to coping.

A second definition of withdrawal involves the active avoidance of social contacts. Altman's (1975) boundary-control model of privacy postulates that the individual may actively seek or thwart social interactions to maintain an appropriate level of social stimulation. Schmidt et al. (1979) found that the ability to attain the desired degree of privacy and the freedom to get away from the residence were important predictors of the self-reported perception of crowding in the residence. These clearly are factors that involve withdrawal or escape from a restricted setting. Kutner (1973) manipulated group size, interpersonal distance, and visual body exposure. He found no relationship between any of these factors and self-rated anxiety; however, behaviors that protected the subject from the visual scrutiny of others increased over time for the high-visual-exposure groups. Kutner suggested that density did not increase anxiety because subjects were able to implement behaviors that eliminated the threat. He postulated that when these behaviors become ineffective in shielding the individual from surveillance by others, anxiety may be increased by the number and proximity of people in the room; that is, density is expected to intensitfy the problem of visual exposure.

A final aspect of behavioral control and coping is anticipatory responding to density. Crowding is expected to occur when the individual is unable to take action to cope with an impending high-density situation following prior warning of the condition. Stokols (1976) noted that anticipation of and preparation for conditions that are potentially stressful are important components of the behavioral constraint explanation. The ability to implement learned responses based on prior experiences with an environmental condition may help mitigate the potentially negative effects prior to the actual onset of a stressor (Appley & Trumbull, 1967; McGrath, 1970). Similarly, Lazarus (1966) has noted that the psychological stress that is experienced by an individual is inversely proportional to the person's anticipated capability to deal with the stressor.

Although the research on anticipatory responses and crowding is sparse, some interesting results have been obtained. Schopler and Walton (Note 1) manipulated anticipated interference by leading subjects to expect tasks that were either structured or unstructured. They reasoned that group structure would act as a regulatory mechanism of interactions between group members

involved in performing a task. Hence, the behavior–outcome relationship (outcome effectance) would be clearly specified. The lack of an established task and group structure was expected to be related to less situational control and a greater potential for interference with other group members, since rules for controlling group interactions and for completing tasks were unspecified. Schopler and Walton found a marginally significant trend: Subjects who believed that the task situation would be unstructured felt more crowded than subjects expecting a structured group. It was suggested that the degree of structure affects anticipated control over the situation.

Baum and Greenberg (1975) conducted a study in which subjects believed that they would be interacting in either 4- or 10-persons groups in experimental rooms of the same size. Although all conditions actually involved groups composed of a subject and two confederates, each subject believed that the entire 4- or 10-person group would meet. It was found that subjects anticipating 10-person groups perceived the room to be more crowded than did those anticipating 4-person groups. Individuals expecting large groups tended to select corner seats in the room, positions from which they could maintain the greatest control over spatial intrusion. Additionally, subjects in the 10-person condition tended to look at the confederates less often and rated each successive confederate entering the room progressively more negatively.

In summary, the evaluation of crowding is related to a loss of behavioral control when physical density creates a condition in which behaviors are interrupted and the attainment of goals is blocked. Research has been presented, however, that indicates that the expectation of control over an aversive stimulus, even in the absence of objective control, is sufficient to forestall negative reactions to the environment. Finally, evidence has been presented that suggests that coping responses initiated prior or subsequent to the onset of a dense condition in which behavioral interference and goal blocking are likely to occur can, in some instances, mitigate negative responses to environmental conditions. Ineffective coping with conditions related to density, on the other hand, is expected to increase evaluations of a setting as crowded.

Cognitive Control

Behavioral control refers to responses that either produce direct action on the environment or allow the individual to actively avoid negative conditions, whereas cognitive control is concerned with the way events or conditions are interpreted by the individual. In this regard, Averill (1973) has defined two elements: information gain and appraisal. Information gain refers to the predictability of a stressor and the anticipation of an aversive event. However, in contrast with the anticipatory responses discussed in the previous section, information gain does not involve any direct action on the environment. Rather, it is concerned with cognitive preparation for an event. Appraisal, the second component, involves the interpretation and evaluation of events. Johnson (1974) defined the term *outcome realization* as the evaluation and interpretation of outcomes, a concept similar to appraisal.

A review of Averill (1973) shows that information concerning the occurrence of an aversive stimulus is related in a complex way to stress. He cited animal studies suggesting that prior warning often increases stress (e.g., overt behavioral disturbances), which can be reduced by using available avoidance responses. Other studies have demonstrated a clear preference for signaled versus unsignaled aversive stimulation, even when escape or avoidance was not possible (e.g., Badia & Culbertson, 1972; Perkins, Seymann, Levis, & Spencer, 1966). Studies with human subjects have also shown a complicated pattern of results. Geer and Maisel (1972) found that subjects who could predict the occurrence of a stressor exhibited greater autonomic responding than did control subjects. Epstein (1973) suggested that although prior warning of an aversive stimulus may initially increase stress, the subsequent generation of accurate expectancies may facilitate habituation, ultimately reducing stress. Monat,

Averill, and Lazarus (1972) found that subjects preferred to know when an electric shock would occur and exhibited less anticipatory responding when this information was not provided. Similarly, Starke (1973) found that the predictable condition led to lower galvanic skin response rates and less subjectively reported discomfort than the unpredictable condition. Staub and Kellett (1972) observed that subjects receiving information concerning the objective and subjective qualities of an aversive stimulus (electric shock) tolerated a more intense level of stimulation before rating it as painful than the level tolerated by subjects provided with only partial or no information. Presumably, this information allows the individual to develop accurate expectancies concerning objective danger and subjective sensation. Hence, information gain functions in two ways. First, it signals the onset of a stressor so that possible cognitive preparation can be initiated. Second, it allows the individual to generate accurate expectancies concerning the stimulus, resulting in eventual habituation to arousal. Lack of appropriate avoidance responses or the generation of inaccurate expectancies may increase the perceived stressfulness of an environmental stimulus (cf. Averill, 1973; Lazarus, 1966).

The importance of information gain is apparent from the literature on human crowding. The role of norms in providing a basis for situational expectancies and predictability was discussed in a previous section. The anticipation of inappropriate spatial violations, the inability to control spatial boundaries, or the blocking of situationally appropriate behaviors may be related to an increase in perceived crowding. Schopler and Walton (Note 1) found a marginally significant trend in which subjects anticipating unstructured groups felt more crowded than groups with well-specified structures. Presumably, unstructured situations increase the potential for social interference. Baum and Greenberg (1975) observed that when subjects anticipated interactions in a dense setting, perceived crowding increased and anticipatory responding was enacted. The behaviors and perceptions observed in these studies were clearly based on the subject's assessment of impending conditions, since expected density levels were never experienced (cf. Lazarus, 1966; Stokols, 1976). Langer and Saegert (1977) reported that subjects felt less uncomfortable and crowded when they were given information about the potential arousal and anxiety they would experience before entering a dense supermarket.

A second effect of information gain is to focus the attention of subjects on the impending occurrence of a stimulus. Averill (1973) has suggested that stimulus overload created by increased vigilance may increase the level of stress experienced prior to the onset of an aversive stimulus. Monat et al. (1972) found that information concerning the time of occurrence of a stressor (indicated by external cues) resulted in increased anticipatory stress for human subjects. Geer and Maisel (1972) also found increased physiological responses to impending stressors by subjects who could predict onset. The results of the Baum and Greenberg (1975) and Schopler and Walton (Note 1) studies can also be interpreted as the consequence of prior warning that effectively focused the subject's attention on the expected qualities of a high-density or potentially uncontrollable situation. This is especially true of the Schopler and Walton study, since subjects in the unstructured condition were initially unaware of what specific conditions they would be facing.

Stokols et al. (1973) have suggested that certain personal and social factors sensitize the individual to actual or potential spatial constraints in a setting. The person may be predisposed to attend to various environmental cues that serve to forewarn him or her of possible restrictions created by social density. Increased sensitivity to the environment is expected to increase the likelihood that a setting will be evaluated as crowded. For example, Schopler and Walton (Note 1) found that subjects with an external locus of control were more likely to evaluate a setting as crowded than were internals. Externals may be more likely to attend to cues that signal a loss of control over the en-

vironment. Schmidt et al. (1976) found that various subcultural groups attended to different factors in their evaluation of crowding. Schmidt (in press) observed that subjects reporting that spatial factors were important considerations in the selection of their current residences were more likely to evaluate the setting as crowded. He postulated that this may reflect an attentional focus on space and spatial restrictions that subsequently occur. Rapoport (1975) suggested that crowding research should focus on density that functionally affects the individual rather than on the gross physical measurements that are typically taken. Clearly, predispositions that focus the individual's attention on the external environment increase this functional density.

Milgram (1970) proposed that experiences in large urban areas may lead to expectations that evoke long-term cognitive strategies for dealing with social overstimulation and the resultant cognitive overload. Environmental cues that forewarn the individual of potential stimulus overload from social sources may elicit these strategies. For example, Saegert's (1973) department store study (cited previously) offers support for this idea; subjects attended to less detail in the setting. Baum and Greenberg (1975) found that subjects anticipating a dense situation tended to look at others in the setting less often than those anticipating a relatively low-density setting. Sundstrom (1975) also found that goal blocking, a consequence of density in other research, led to less attention by subjects to others present in the room. These behaviors allow the individual to tune out potentially stressful aspects of the setting.

The human crowding literature that has been reviewed demonstrates that information gain given as prior warning of an impending dense situation serves to increase the likelihood that a setting will be evaluated as crowded. The research has suggested that habituation to the arousal resulting from the expectation of high density may be caused by the enactment of coping strategies that perceptually reduce the perceived impact of density by focusing the individual's attention away from the immediate environment. Conditions or predispositions that focus the individual's attention on the implications of density are expected to increase the likelihood of crowding evaluations (cf. Averill, 1973; Baum & Greenberg, 1975; Schmidt, in press). Additionally, anticipation of a dense situation was shown to lead to avoidance behaviors that demonstrated an active attempt to seek protection from anticipated problems. These behaviors suggest that much of the contradictory experimental evidence relating predictability, autonomic arousal, and subjective stress can be reconciled by considering information gain in conjunction with the second component of cognitive control, appraisal.

Appraisal refers to the way that individuals evaluate and interpret events and is related to the subsequent affective responses that can be expected. This aspect of control is important, since crowding is typically defined as a negative affective reaction to conditions created by density. When actual or potential goal blocking can be attributed to the density of a setting, one would expect the individual to evaluate the situation as crowded (Baum & Greenberg, 1975; Stokols et al., 1973; Sundstrom, 1975). Lazarus (1966) noted that stress occurs when the individual anticipates an inability to cope with an impending situation. If the person judges that interference or overload created by density cannot be effectively dealt with, the perception of crowding is increased (cf. Kutner, 1973). Again, one is dealing with a cognitive evaluation that is separate from any behavioral responses.

Stokols (1976) noted that the critical factor in psychological stress is the individual's belief that he or she is unable to exert control over a situation. Crowding implies that the individual perceives an inability to deal with conditions created by density and hence anticipates or experiences goal blockage, spatial restrictions, or cognitive overload. Cognitive or behavioral coping responses are ways of preparing for and dealing with these conditions. Appraisal may, therefore, involve a series of environmental assessments, responses, and reassessments (cf. Stokols,

1972b, 1976). However, cultural and sex-specific norms have been shown to shape these assessments; that is, different behavioral and spatial standards are used to appraise impending or ongoing situations (Anderson, 1972; Draper, 1973; Epstein & Karlin, 1975; Freedman et al., 1972; Hall, 1966; Schmidt et al., 1976; Watsen & Graves, 1966).

A number of studies have demonstrated the effect of appraisal on environmental evaluations. Schopler and Walton (Note 1) found that subjects expecting to interact in unstructured groups reported more perceived crowding than subjects expecting a well-specified group structure. They suggested that this difference may be attributable to the subject's appraisal that the unstructured situation would be less controllable. Sherrod (1974) concluded that the stress of interacting in a high-density situation was reduced by simply making subjects believe that they were free to leave. Desor (1972) found that entrances and partitions in a model room were viewed as ways of maintaining control over interactions (cf. Altman, 1975) and affected the perception of crowding. Partitions and entrances should lead to the appraisal that a setting is controllable.

In summary, appraisal is a cognitive evaluation that is affected by the individual's anticipation of his or her ability to deal with an impending situation. The perception of ability to deal with an impending noxious stimulus can reduced both stress and objective ratings of the aversiveness of the negative affective response to a setting when the individual believes that density-related conditions will create an uncontrollable situation.

Decisional Control

The final element, decisional control, is defined by both Averill (1973) and Johnson (1974) as choice in the selection of specific outcomes or goals. It is the primary component of control in Brehm's (1966) theory of psychological reactance. Our discussion of this element of control is brief, since in the literature on crowding, a limitation of choice or freedom is tantamount to a loss of both behavioral and cognitive control.

From the perspective of the behavioral constraint explanation, crowding is believed to occur when the individual is unable to attain desired outcomes or goals in a setting because density has functionally blocked the behavior–goal relationship. In this way, both behaviors and goals are restricted. Goal blocking and behavioral interference have been related to an increased perception of crowding when density is a viable cause (Proshansky et al., 1970; Saegert, 1973; Schmidt, in press; Schmidt et al., 1979; Wicker et al., 1976). These restrictions functionally limit the options available to an individual in a setting, reducing decisional control and increasing negative affect and psychological reactance.

Brehm (1966) and Wortman and Brehm (1975) noted that the importance of the outcomes that were restricted was a central factor in determining the magnitude of the reactance that was evoked. The blocking of important or primary behavioral alternatives or goal options is expected to produce more reactance than options that are of little personal importance. A similar logic has been proposed by Stokols (1976) in relation to the evaluation of crowding. He suggested that perceived crowding tends to be of greater intensity in primary versus secondary environments. Primary environments include those settings in which the individual spends a great deal of time (e.g., work or residential areas), is engaged in relatively long-term interactions with others, and is involved in a number of personally important activities. Secondary environments are locations in which interactions with others are relatively transitory, anonymous, and of generally less consequence (e.g., public transportation, shopping facilities, etc.). Stokols suggested that goal blocking or behavioral interference in primary environments may involve the limitations of important goals and activities. Hence, the impact of dense or related conditions is more critical, and the perception of crowding should be of a greater magnitude.

Altman's (1975) boundary-control model

of privacy suggests that a loss of decisional control is related to the evaluation of crowding. This theoretical perspective posits that the individual in a social situation decides on an optimal level of social interaction or stimulation. This desired level is either attained or blocked, depending on conditions in the setting (e.g., density, spatial restriction, etc.). If situational conditions force a level of social interaction or stimulation beyond that desired by the individual, an evaluation of crowding is expected to result.

Decisional control refers to the ability of the individual to select outcomes or goals in a social situation. However, in the crowding literature, decisional control is tantamount to behavioral control, since restricted behaviors and blocked goals functionally limit the activities that are possible in an environment. Similarly, an appraisal that a setting is uncontrollable or prior warning of impending conditions may also indicate a reduction in decisional control. The increased likelihood that a setting will be evaluated as crowded is expected to occur if density is a viable cause of these restrictions of behavior and goal alternatives.

Personal Control and the Attribution of Crowding

Although the literature on personal control and the literature on human crowding fit together reasonably well, it is clear that the evaluation of crowding within a specific setting may be the result of deficiencies in a number of control components. The results from a number of the crowding studies are explicable by using one or more of these elements. Certainly the consequence of living and interacting in high-density environments is likely to be a loss of some degree of control over behaviors and the pursuit of goals. It is important at this point to examine the specific cognitive processes that are involved when an individual experiences or anticipates a loss of control and evaluates a setting as crowded.

The literature reviewed previously indicates that a lack of behavioral control or the appraisal that a situation is uncontrollable is related to increased levels of self-reported stress and indices of physiological arousal (e.g., Corah & Boffa, 1970; Geer et al., 1970; Glass & Singer, 1972; Staub, Tursky, & Schwartz, 1971). Similarly, the human crowding literature has suggested that environmental conditions that reduce an individual's control (i.e., goal blocking, behavioral interference, and stimulus overload) also lead to more self-reported stress and arousal (e.g., Saegert, 1973, 1975; Stokols et al., 1973; Sundstrom, 1975; Valins & Baum, 1974). A subsequent evaluation of the environment as crowded is expected to result when density levels are sufficiently high; this evaluation may be tied to loss of control.

A number of studies have demonstrated an association between density and arousal, as measured by skin conductance (Aiello, Epstein, & Karlin, 1975), heart rate and blood pressure (D'Atri, 1975; Evans, 1975), and palmar sweat (Saegert, 1975). However, it is unlikely that the relationship between density and arousal is as simple as these results suggest. In these studies, conditions indicative of some social impact are often confounded with density. It is unclear whether density causes arousal or whether arousal is due to a concomitant consequence. Certainly the behavioral constraint and cognitive overload explanations suggest the latter possibility. Sundstrom (1975) observed that self-reported stress and irritation were not related to density when goal blocking and behavioral interference were manipulated independently of this density. These latter conditions were also related to increased arousal in previous studies (e.g., Mandler, 1964; Wortman & Brehm, 1975).

Findings such as these suggest that physical density may have an indirect effect on arousal. Previous articles have also indicated that anticipated problems precipitated by density may lead to the appraisal that a situation is uncontrollable, thus creating stress and arousal. However, even in this case anticipated goal blocking and behavioral interference are the critical factors resulting in the perception of crowding.

Arousal and stress created by a loss of control over the environment are similar to

what Brehm (1966) has called psychological reactance. Goal blocking, behavioral interference, and stimulus overload are often density-related consequences that decrease an individual's situational control and hence are expected to elicit some degree of reactance. We predict a lower level of arousal and stress associated with a relatively controllable setting and greater arousal and negative affect related to uncontrollable situations. Additionally, we expect the actual or anticipated ability of the individual to cope with or to eliminate the source that threatens personal control to have a direct relationship to the magnitude and duration of the reactance that is experienced (cf. Brehm, 1966). Although reactance theory posits effects that may be attributed to a loss of control over the environment, we expect similar effects for situations in which one finds a general lack of control as well. Presumably, in these settings a lack of control manifests itself in the inability to deal with a situation or to pursue activities and goals. Hence, lack of control in a setting should produce the same arousal and stress effects that have been found in situations in which conditions have precipitated a loss of environmental control. The previous discussions on cognitive control suggest that the individual may manifest initial stress if lack of control is expected and the situation is thus appraised in this way. For the sake of brevity in this discussion, we assume that both a lack and a loss of control are similar conditions; that is, both create increased levels of arousal and can be produced by situational density.

Social psychological theory and research suggest that the link between arousal and the evaluation of a setting as crowded may involve a relatively complex cognitive process. Current research indicates that when arousal is experienced by the individual, it is subsequently labeled as consistent with the context of the situation. Hence, the individual must scan the external environment and attribute arousal to a salient and viable source that is present. Schachter and Singer (1962) conducted a critical investigation of this process. In their initial study, they aroused subjects by injecting them with the drug epinephrine. Subjects were then informed that the drug would cause them to feel aroused (informed condition), would have effects other than arousal (misinformed condition), or would have no noticeable effects (ignorant condition). Schachter and Singer found that subjects were more likely to report emotional states that were consistent with external environmental cues (euphoria or anger) in the misinformed and ignorant conditions than in the informed and placebo (no drug) conditions. They suggested that in the conditions in which subjects did not anticipate arousal, it was necessary for subjects to locate a source in the environment that could be used to cognitively label the internal state. In the informed and placebo conditions, labels were either provided by the experimenter or were unneeded when no physiological arousal was experienced.

While the Schachter and Singer results deal with the cognitive labeling of drug-induced arousal, similar results have been found for situationally induced arousal. These latter studies are more important for the present discussion of crowding, since arousal associated with density and crowding is presumably induced by events occurring in the external environment. The studies that best illustrate the attribution of situationally induced arousal are best described as *misattribution* studies. In these investigations, arousal is induced by making subjects expect the impending occurrence of an environmental stressor (e.g., electric shock). Subjects are led to believe that the real cause of arousal is something else in the experimental setting. Behavioral or self-report measures are then taken to indicate how arousal is labeled. Valins and Ray (1967) found that they could reduce phobias about snakes by convincing subjects that their arousal was due to impending electrical shocks rather than to snakes. Storms and Nisbett (1970) found that they could reduce insomnia by making subjects believe that their arousal was due to a pill (placebo) administered to them rather than to their personal problems. Finally, Ross, Rodin, and Zimbardo (1969) found

that subjects were more willing to work for monetary rewards than to escape from impending electrical shocks when they were convinced that their arousal was due to the presence of a loud noise rather than to the shocks.

The idea that the evaluation of crowding may be an attributional response to arousal has been a relatively recent development in the literature. A number of studies have offered support for this notion. Freedman (1975) provided evidence suggesting that density acts to intensify positive or negative feelings according to the context of the situation. The environment provides information concerning the interpretation of arousal, and density effectively heightens the level of positive or negative affect. Gochman (1977; see also Keating, 1978; Kalb & Keating, Note 2) conducted a series of studies that directly investigated this labeling process. She found that unfulfilled goals or disconfirmed expectations were related to an evaluation of the setting as crowded when density was salient. She suggested that disconfirmed expectations and unmet goals create a state of arousal (cf. Lazarus, 1966; Mandler, 1964), which is subsequently attributed or misattributed to the most salient environmental condition.

The attributional explanation posits that arousal created by a loss of control may lead to an evaluation of crowding if social factors create some sort of behavioral or perceptual interference and situational density is a salient environmental factor. An interesting test of this approach was provided by Worchel and Teddlie (1976). In their study room size (spatial density; Loo, 1973), close or far interaction distance, and the presence or absence of picture distractors on the walls were manipulated as independent variables. They found that the perception of crowding was greatest when density was high, when interaction distance was close, and when picture distractors were not present. When interaction distance was close and distractions were present, the room was rated as relatively less crowded. Worchel and Teddlie suggested that close interaction distances caused spatial violations that were associated with increased levels of arousal (Felipe & Sommer, 1966; Hall, 1966; Sommer, 1969). When the subject searched the setting for a cause of the arousal, attention was drawn to either density or to the visual distractors. Hence, when attention was focused away from room density by the picture distractors, arousal was not attributed to density and an evaluation of crowding was less likely. However, when density was salient, the setting was evaluated as significantly more crowded. Langer and Saegert (1977) found that subjects performing an experimental task in a dense supermarket reported feeling less crowded and more comfortable when they were told that they might become aroused and anxious than when they were uninformed. Hence, information gain concerning potential internal states may partially alleviate negative affect attributable to dense settings.

Research investigating the attribution approach to crowding has suggested that the evaluation of crowding may either be a veridical or a nonveridical response to the environment; that is, density may create conditions that lead to increased arousal and a subsequent evaluation of crowding, or arousal may be misattributed to density when it is merely a salient, although noncausative, factor in the setting (Keating, 1978). In the present discussion, we are most interested in the former case (when crowding is a veridical response based on the impact of density), since this has been the primary theoretical and empirical focus in the past.

Control–Attribution Model of Human Crowding

Figure 1 is an illustration of the suggested process. Previous research and theory has described crowding in terms that imply a loss of control over the environment. Although absolute density has been shown to have an inconsistent relationship to the cognitive evaluation of crowding, functional density in its impact on the individual's activities and behaviors appears to be important (Rapoport, 1975). Ample evidence has been presented that indicates that loss of control is associated with physiological

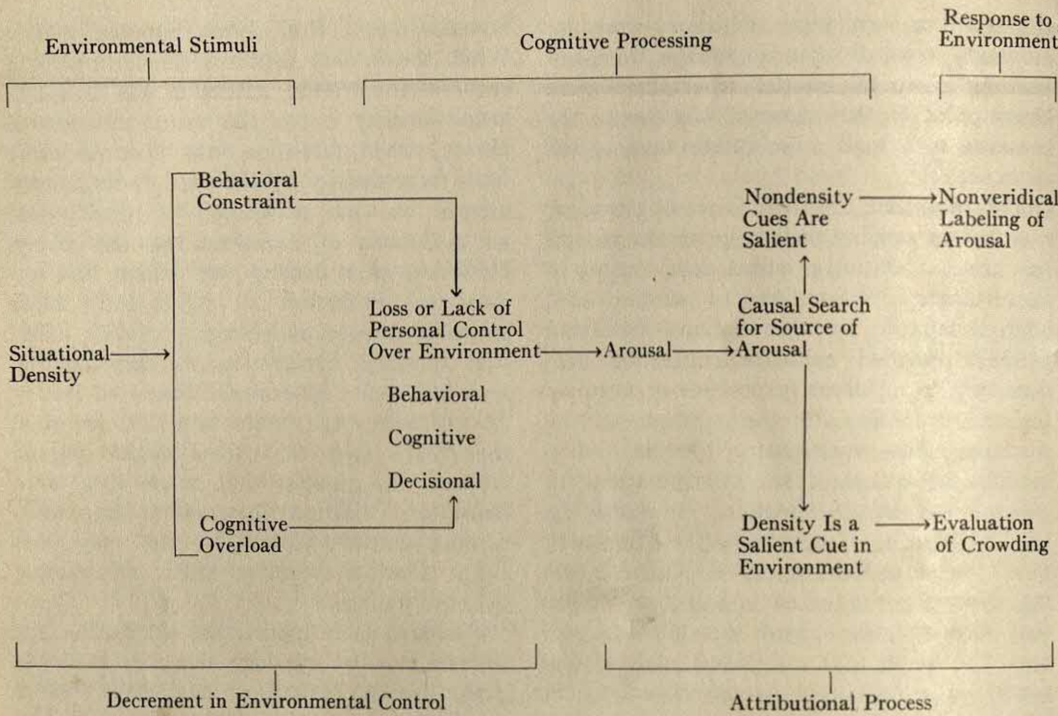

Figure 1. A control-attribution model of human crowding.

and self-reported arousal, especially when the situation creates a decrement in behavioral control or the appraisal that a situation is uncontrollable. Similarly, goal blocking, behavioral interference, and stimulus overload have been viewed as sources of arousal or stress in previous articles. This arousal state that is produced by a lack of or loss of control over the environment is a necessary antecedent to the subsequent attributional process.

The attribution segment of the diagram details the cognitive events that are thought to take place when arousal is experienced and a cognitive label is needed. The individual scans the environment in an attempt to find a viable source of the internal physiological state. However, increasing levels of arousal lead to a restriction of the number of environmental cues that are considered and of the amount of information incorporated in the individual's decisions and judgments (Easterbrook, 1959; Schroder, Driver, & Streufert, 1967). Hence, the salience of various environmental cues becomes important. Specifically, cues that are salient and are perceived as viable causes of the arousal state are selected because of the limited attentional focus maintained by the individual (cf. Worchel & Teddlie, 1976). These cues may then provide the cognitive label for the arousal that is experienced. In the present case, crowding is viewed as an attributional label when density is salient and has acted to functionally limit an individual's personal control over a setting. This model clearly allows for either veridical or nonveridical labeling of arousal generated by density-related conditions, although the former condition is our primary interest in this article.

The present model makes some distinctions that are relevant to follow-up research in the area of human crowding. Figure 1 suggests three distinct stages in the evaluation of crowding: the presence of environmental stimuli and objective environmental conditions, cognitive processing requiring an assessment of personal control and the subsequent attributional phase, and the final evaluation of crowding. Although it may seem tenuous to classify behavioral con-

straint or cognitive overload as components of environmental stimuli, this is precisely the way these concepts have been operationalized in the experimental research; they are objectively manipulated conditions. In this sense, previous views of crowding have involved a simple stimulus–response explanation for crowding. Objective environmental events or stimuli lead to the evaluation of crowding. The control–attribution approach includes these previous explanations along with indications of interceding cognitive processes. It is clear that an investigation of the nature of these processes, especially of the components of personal control, is a necessary step for a full understanding of crowding. It seems important to map conditions such as behavioral constraint and cognitive overload onto subjective control and to investigate individual-difference variables (e.g., demographic variables, stable personality dispositions, etc.) as mediators of this relationship. With this type of research it should be possible to make more accurate predictions concerning the evaluation of crowding than would be allowed by a simple stimulus–response model and to tie together both physical environmental stimuli and subsequent cognitive evaluations.

Social psychological theory and the experimental research on personal control suggest that the literature on human crowding is explicable by using established psychological principles. The application of these more general phenomena offers both a consolidation of diverse explanations of crowding and a logical thread tied to larger empirical bases. However, a clear need for more detailed study of the impact of physical and social conditions on behaviors and on subsequent evaluations such as crowding has been established. It is these additional studies that will help to map the relationships among objective environmental conditions and the psychological effects they produce.

Therapeutic Videotape and Film Modeling: A Review

Mark H. Thelen, Richard A. Fry,
Peter A. Fehrenbach, and Nanette M. Frautschi
University of Missouri—Columbia

This article reviews research involving the use of videotape and film modeling in clinical and analogue settings. Most of the research has been on phobias, test anxiety, dental and medical stress, and interpersonal skills. Critical methodological issues and the relevance of this research to modeling theory are also discussed. The need for improved methodology and the application of videotape and film modeling in more clinical populations is emphasized.

Symbolic modeling in the form of films or videotapes was the logical outgrowth of the documented effects of live modeling in therapy (Bandura, 1969; Geer & Turtletaub, 1967; Sarason, 1968). It is likely that the cognitive processes identified as important in the effects of live modeling—such as verbal and imaginal coding and rehearsal (Bandura, 1977; Bandura, Blanchard, & Ritter, 1969)—can as well occur as a function of observing a filmed model. There is little reason to believe that the symbolic processes are particularly different as a function of observing a live versus a filmed model (Bandura & Barab, 1973).

Film and videotape modeling has several advantages over live modeling. The availability of filmed and videotaped media provides the opportunity to capture naturalistic modeling sequences that would be difficult to create in clinic settings. And of course the therapist has greater control over the composition of the modeling scene because the film or videotape can be reconstructed until the most desirable scene is produced. These media also permit the convenient use of multiple models, repeated observations of the same model, reuse of the films or videotapes with other persons, and self-administered treatment sessions. In addition to these advantages, there is the benefit of efficiency. More clients can be treated, and there is less demand on the time the professional spends with each client.

This article reviews research on the efficacy of videotape and film modeling, herein referred to as symbolic modeling (SM), in the treatment of clinical and clinical-like (i.e., analogue) problems. One purpose of this article is to review studies that test the efficacy of SM by comparing either SM alone, or SM combined with other treatment components, with control conditions. Studies that compare SM with other treatment techniques or components also are reviewed. Another purpose is to identify procedural and conceptual issues relevant to SM research. Finally, attention is given to methodological considerations that are critical to eventually discerning the effects of SM in a variety of therapeutic contexts and with various clinical groups.

Effects of Therapeutic Symbolic Modeling

Table 1 summarizes the studies that have investigated therapeutic SM. Note that the studies are grouped according to the behavior under investigation, beginning with phobias and followed by test anxiety, dental and medical stress, interpersonal skills, and other clinical problems. The second column in Table 1 specifies whether the subjects were adults or children and the target behavior under investigation. In the third column,

Table 1
Results of Symbolic-Modeling Studies

Study	Subjects and target behavior	Symbolic modeling versus control	Symbolic modeling versus comparison treatment	Generalization	Maintenance
		Phobias			
Bandura & Barab (1973)	Adults, snake fear	SM > irrelevant film on B, physiological, & SR*		Yes	Not assessed
Bandura, Blanchard, & Ritter (1969)	Adults, snake fear	SM + relaxation > no treatment on Att, B, & SR*	SM + relaxation > desensitization on SR & = desensitization on B; SM + relaxation < live modeling + participation on Att, B, & SR*	Yes	Yes (1 month)
Bandura & Menlove (1968)	Children, dog fear	SM > irrelevant film on B*		Yes	Yes (1 month)
Denney & Sullivan (1976)	Adults, spider fear	SM > no treatment on B & SR;* SM + relaxation > no treatment on B & SR*	SM > spider-only film on B & SR	Not assessed	Not assessed
Hill, Liebert, & Mott (1968)	Children, dog fear	SM > no treatment on B		Not assessed	Not assessed
Kornhaber & Schroeder (1975)	Children, snake fear	SM > no treatment on Att & B*		Not assessed	Not assessed
Lewis (1974)	Children, water fear	SM > irrelevant film on B; SM + guided participation > irrelevant film on B	SM < guided participation on B; SM + guided participation > guided participation on B; SM + guided participation > SM on B	Yes	Not assessed
Lira, Nay, McCullough, & Etkin (1975)	Adults, snake fear	SM > no treatment on Att & = no treatment on B & SR	SM > snake-only film on Att & = snake-only film on B & SR; SM < rehearsal on B & = rehearsal on Att & SR	Not assessed	Yes (2 months)
Morris, Spiegler, & Liebert (1974)	Adolescents, snake fear	SM > irrelevant film on SR*	SM > snake-only film on SR*	Not assessed	Not assessed

Table 1 (*continued*)

Study	Subjects and target behavior	Symbolic modeling versus control	Symbolic modeling versus comparison treatment	Generalization	Maintenance
		Phobias (*continued*)			
Spiegler, Liebert, McMains, & Fernandez (1969)					
Experiment 1	Adults, snake fear	SM > no treatment on B*[a]		Not assessed	Yes (1 month)
Experiment 2	Adults, snake fear	SM > no treatment on B		Not assessed	Not assessed
Experiment 3	Adults, snake fear		SM + relaxation > relaxation on B	Yes	Yes (1 week)
Weissbrod & Bryan (1973)	Male children, snake fear		SM > SM with snake replica on B	Not assessed	Yes (2 weeks)
		Test anxiety			
Andrews (1973)	Adults, test anxiety	SM + relaxation > no treatment on B & = no treatment on SR		Not assessed	Not assessed
Jaffe & Carlson (1972)	Adults, test anxiety	SM > no treatment on B & SR*		Not assessed	Not assessed
Malec, Pack, & Watkins (1976)	Adults, test anxiety	SM > no treatment on SR*		Not assessed	Not assessed
Mann (1972)	Adults, test anxiety	SM > no treatment on B & SR; SM + relaxation > no treatment on B & SR	SM = SM + relaxation on B & SR	Not assessed	Yes (6 weeks)
		Dental–medical stress			
Machen & Johnson (1974)	Preschoolers, dental fear	SM > control on B	SM = desensitization on B	Not assessed	Not assessed
Melamed, Hawes, Heiby, & Glick (1975)	Children, dental fear	SM > irrelevant film on B & staff rating & = irrelevant film on physiological & SR		Not assessed	Not assessed
Melamed & Siegel (1975)	Children, hospital fear	SM > irrelevant film on physiological, B, SR,* & parent ratings*		Not assessed	Yes* (3 weeks)
Melamed, Weinstein, Hawes, & Katin-Borland (1975)	Children, dental fear	SM > irrelevant task on B & staff rating & = irrelevant task on SR		Not assessed	Not assessed

O'Connor (1969)	Preschoolers, social isolation	SM > control film on B		Not assessed	Not assessed
O'Connor (1972)	Preschoolers, social isolation	SM > control film on B; SM + shaping > control film on B	SM > shaping on B; SM + reinforcement > reinforcement on B; SM + reinforcement = SM on B	Not assessed	Yes (3 weeks)
Rathus (1973)	College students, unassertiveness	SM + 2 components > placebo on B & SR;* SM + 2 components > assessment only on B & SR*		Not assessed	Not assessed

Table 1 (*continued*)

Study	Subjects and target behavior	Symbolic modeling versus control	Symbolic modeling versus comparison treatment	Generalization	Maintenance
		Interpersonal skills[b] (*continued*)			
Thelen, Fry, Dollinger, & Paul (1976)	Male delinquents, interpersonal behavior	SM + rehearsal > control tapes on staff ratings & = control tapes on teacher ratings		Not assessed	No (2 weeks)
		Other clinical problems			
Baker, Udin, & Vogler (1975)	Adult males, alcoholism		SM < self-confrontation + behavioral counseling on B	Not assessed	No (6 weeks[g])
Reeder & Kunce (1976)	Adults, heroin addiction		SM + discussion > lecture + discussion on B	Not assessed	Yes[h]
Thomas (1974)	Children, classroom attention	SM > no treatment on B		Not assessed	Not assessed
VanCamp (1972)	Adults, marital conflict	SM = practice on B & SR		Not assessed	Not assessed
Wincze & Caird (1976)	Adult females, sex anxiety	SM > waiting list on SR*	SM < systematic desensitization on SR*	Not assessed	Not assessed

Note. SM = symbolic modeling, B = behavioral measure, SR = self-report measure excluding attitude measures, and Att = attitude measure; > indicates greater improvement, = indicates no differences, and < indicates less improvement.

[a] SM without narration group = no treatment on B; SM + narration group > no treatment on B.

[b] When a condition consisted of two or more components, in addition to SM, only the number of components is indicated. The following components were used in one or more of the studies: instructions, rehearsal, feedback, homework, relaxation, discussion, reinforcement, and communication training.

[c] Similar results were obtained at a 3-month follow-up.

[d] Posttest data were collected 6 weeks after intervention.

[e] SM + rehearsal + instructions > rehearsal + instructions on B* & = rehearsal + instructions on SR; SM + rehearsal + instructions > rehearsal on B* & = rehearsal on SR; SM + rehearsal > rehearsal on B* & = rehearsal on SR; SM + rehearsal < rehearsal + instructions on some B measures and > rehearsal + instructions on other B measures, & = rehearsal + instructions on SR.

[f] Because of its importance in this study, narration is reported as a separate component. It is not considered as a separate component for the other studies.

[g] Similar results were obtained at a 6-month follow-up.

[h] Posttest data were collected 90 days and 180 days after intervention.

* Results were mixed.

results are reported that involved a no-treatment, attention, or placebo control. The treatment was either SM alone or SM plus one or more treatment components (e.g., instructions or behavioral rehearsal). Column 4 lists results involving a comparison treatment that was composed of one or more components. As with column 3, the SM condition involved either SM alone or SM plus one or more additional components. The last two columns of Table 1 contain information pertinent to generalization and maintenance—whether or not these factors were assessed and, if so, whether the results were affirmative or negative. It was also deemed useful to specify the time interval between the treatment intervention and the assessment of maintenance.

The results, as they are summarized in Table 1, pertain to between-groups differences, usually based on posttest differences or differences in change scores between groups. Also, it should be noted that in all studies the symbol *greater than* (>) is meant to indicate greater improvement in the clinical behavior. For example, the first study listed is by Bandura and Barab (1973). The table shows that SM was greater than an irrelevant film. This should be interpreted to mean that the SM group improved more than the control group, that is, the SM group showed greater fear reduction. An equal sign (=) indicates no differences between groups.

It should be noted that in this portion of the article no attempt is made to qualify the results because of methodological considerations. Methodology issues are discussed in a later section.

Phobias

As can be seen in Table 1, research on phobias has been done with both adults and children; snake fear is the most common problem studied. The third column in the table reveals that SM, both with or without added components, had a positive treatment effect in comparison with the no-treatment and irrelevant-film control conditions. The fourth column reveals that SM compares favorably with other treatment components, especially if SM is combined with relaxation or guided participation. It also is apparent from the last two columns of Table 1 that, when assessed, generalization and maintenance effects were obtained.

Text Anxiety

Four studies have been reported that appraised the effects of SM, often involving vicarious systematic densensitization, on test-anxious adults. Table 1 reveals that generally positive effects have been obtained for SM when compared with control conditions; however, no research has compared SM with other treatment components. None of these studies reported an assessment of generalization, and only one study (Mann, 1972) assessed the maintenance of the treatment effects. Mann found that changes were maintained 6 weeks after treatment.

Dental–Medical Stress

Symbolic modeling has been used to alleviate stress and disruptiveness in dental and medical patients, typically among people who had no prior dental work or surgery. Prior to the actual dental work or surgery, the modeling film or videotape is shown to each treatment subject. Looking at the column of Table 1 that compares SM with control groups, it can be seen that all but one of the studies (Shaw & Thoresen, 1974) used SM alone, and the studies typically did not involve other components. It appears that SM often is effective in comparison with controls according to behaviorally based measures, but the results are less clear for measures obtained from staff ratings, peer ratings, and self-report.

It is apparent from column 4 that only three studies (Machen & Johnson, 1974; Shaw & Thoresen, 1974; Wroblewski, Jacob, & Rehm, 1977) have investigated the effect of SM relative to other treatment components. Given the mixed findings of these few studies, a definitive statement is not possible.

Generalization as such has not been assessed by researchers in this area; however, the dependent measure was often taken in a natural setting, so that additional measures to assess generalization may not have been necessary. Four studies (Melamed & Siegel,

1975; Shaw & Thoresen, 1974; Vernon, 1973; Wroblewski et al., 1977) appraised maintenance of treatment effects for periods ranging from 3 weeks to 3 months, and all of these studies found at least some indication of maintenance.

Interpersonal Skills

Symbolic modeling has been used to facilitate assertiveness, social interaction, and the development of other appropriate social skills. This area of research contains the largest number of studies involving SM. Studies have been done with children, adolescents, college students, and adult psychiatric patients. A summary of the results depicted in the third column of Table 1 shows that SM alone was generally more effective than the control conditions, although two studies found no differences between SM and control conditions on social interaction in socially isolated preschoolers (Gottman, 1977; Jakibchuk & Smeriglio, 1976). With five exceptions SM plus other treatment components, often three or four in number (see Footnote b in Table 1), typically was greater in effect than the control condition. In three of these five studies, the failure to obtain significant differences between a treatment condition including SM and a control condition was based on self-report measures (Curran, 1975; Hersen, Eisler, Miller, Johnson, & Pinkston, 1973; Burrs & Kapche, Note 1).

Of the studies that involved SM plus components compared with a control group, nearly all (13 of 15 studies) contained rehearsal. Five studies contained an instruction component, 5 a feedback component, 4 a discussion component, 3 a homework component, 2 a reinforcement component, and 1 a communication training component. Of the 13 studies that contained SM plus rehearsal, all but 5 also contained other components. Of these 5 studies, 3 found SM plus rehearsal to be more effective than a control condition according to behavioral measures (Eisler, Hersen, & Miller, 1973; Hersen et al., 1973; Jaffe & Carlson, 1976). McFall and Twentyman (1973) reported that SM plus rehearsal resulted in greater improvement than did the control condition, based on a self-report measure, but Hersen et al. found no differences in improvement with a self-report measure. Jaffe and Carlson and Thelen, Fry, Dollinger, and Paul (1976) found SM plus rehearsal to be more effective than control conditions according to staff ratings, but the latter study reported no differences on teacher ratings. Since a number of studies found SM (without additional components) to have significant effects, the results in the above studies may have stemmed from SM alone. No research has independently manipulated SM and rehearsal to appraise their separate and joint effects. Definitive statements about the other components are even more difficult to make because there are few studies and these nearly always involved a multicomponent treatment package.

With the exception of the study by Goldstein et al. (1973), the studies that compared SM with other treatments involved SM plus one or more additional components. The two components most frequently combined with SM were rehearsal (eight studies) and instructions (seven studies). Of the 17 group comparisons involving SM plus one or more additional components in which a behavioral measure was used, the condition that included SM was greater in effect than the comparison treatment in 11 instances and equal to the comparison treatment in 6 instances. However, the condition that contained SM was greater in effect than the comparison treatment in only 1 (Curran, Gilbert, & Little, 1976) of the 10 instances that involved a self-report measure. It appears that SM plus components compares favorably with other treatments, based on behavioral measures, but differences on self-report measures seldom have been found. One explanation for this consistent finding (differences on behavioral but not on self-report measures) is that the behavioral measures typically are obtained during role-playing situations that are similar if not the same as those used in the treatment session. On the other hand, the self-report measures are generally more global measures of social skills. Hersen & Bellack (1976) proposed that there is an "attitudinal lag" between the rapid behavior changes in social skills and subsequent self-assessments.

Also shown in the fourth column of Table 1 are five studies in which the comparison treatment included SM. These studies indicate that SM plus praise is more effective than SM alone in increasing social interaction among socially isolated children (Evers & Schwartz, 1973). However, O'Connor (1972) found that shaping did not make a similar additive contribution to SM alone. Instructions, when included in a treatment package including SM plus rehearsal, facilitated the development of assertive behaviors more than did just SM plus rehearsal (Hersen et al., 1973). However, SM plus instructions was equivalent to SM alone in increasing independent behavior (Goldstein et al., 1973). Also, Jakibchuk and Smeriglio (1976) reported that SM that included first-person, self-guiding comments was superior to SM that included narrative, third-person comments in the sound track. This study is discussed further in a later section. Because of insufficient research on any one component and differences in the dependent measures and populations employed, definitive statements are not possible.

In this area of research generalization usually has not been assessed. Of those studies that assessed generalization, 3 found that SM, at least as one component, facilitated generalization (Hersen, Eisler, & Miller, 1974; Jaffe & Carlson, 1976; McFall & Twentyman, 1973), whereas 2 studies failed to find such effects (Gutride, Goldstein, & Hunter, 1973; Burrs & Kapche, Note 1). However, as with the dental–medical research, studies involving social isolation in preschoolers have assessed the subjects' behavior in natural settings, that is, during children's interactions at nursery school. Generalization to home or other settings has not been assessed. The results concerning maintenance are also very mixed. Of the 13 studies that assessed maintenance, 8 found some evidence for maintenance, and 5 obtained negative results.

Other Clinical Problems

The section of Table 1 labeled Other Clinical Problems contains five studies that focused on problems not encompassed by the previous sections. Since no problem area was investigated more than once, it is impossible to make any definitive observation with respect to the influence of SM. These studies are mainly included for the sake of comprehensiveness and to suggest possible directions for future research.

Conceptual and Process Considerations

Attention is given in this section to variables and processes that have been studied within the context of SM research and that have relevance to theoretical conceptualizations of modeling. Attending to process considerations may facilitate theorizing regarding modeling and further refinement of the applications of SM.

Model–Observer Similarity

The importance of model–observer similarity has drawn the attention of many researchers. Two variables in particular, model age in relation to observer age and the presentation of a coping versus a mastery model, have received considerable attention.

Bandura and Barab (1973) found that adults showed as much snake-fear reduction after observing a child model as subjects who observed a peer model. Fear measures included behavioral, self-report, and physiological measures. Similarly, Weissbrod and Bryan (1973) exposed children to a same-age or a younger model. They found no difference between the two groups on a behavioral approach to snakes measure. Neither of the above two studies contained a model who was older than the subjects. Kornhaber and Schroeder (1975) addressed this question by exposing snake-fearing children to either a child or an adult model. Those subjects who observed a child model demonstrated greater fear reduction on a behavioral avoidance test than those who observed an adult model, but there were no differences on an attitude measure. Furthermore, Kornhaber and Schroeder found that children who observed an adult model did not show greater fear reduction than did a no-treatment control group. Although these studies are limited in number, they are reasonably consistent. With adult subjects, it appears that observing a same-age or child model facilitates fear reduction,

Similarly, children experience the same degree of fear reduction when exposed to peer-age or younger models. However, the observation of an adult model has minimal effects on children. Children may see older models as superior and more capable and therefore may not imitate their approach behavior in a fearful situation. On the other hand, when adults observe children or when children observe younger children, they may be motivated to perform the approach response (Bandura & Barab, 1973). Bandura and Barab reported that adult subjects who observed an adult model showed a positive correlation between fear extinction (based on autonomic responses) and behavioral improvement, which they interpreted as vicarious extinction. In contrast, the adult subjects who observed child models demonstrated little relationship between fear extinction and behavioral improvement, which suggests that motivational factor served to influence approach behavior. In other words, "If that kid can do it so can I." No related research has been done on the effects of model–subject age differences when both model and subject are adults.

The question of the effects of a coping model versus a mastery model is a very complicated one that touches on many of the studies on SM. Many of the studies reviewed used a coping model, but did not manipulate the coping–mastery variable. Additionally, there were variations of the coping–mastery variable. For example, Curran (1975) presented an inappropriate model followed by a competent model.

In a study with snake-avoiding college females, Meichenbaum (1971) suggested that the coping–mastery variable might relate to the broader question of model similarity, which has been shown to enhance imitation (Rosekrans, 1967). In the Meichenbaum study, the coping models displayed initially hesitant behavior, but later fearlessly interacted with the target snake. The mastery models were fearless throughout the modeling sequences, with each model confidently handling the snake. Meichenbaum found that the subjects who observed the coping models displayed significantly greater improvement than subjects in the mastery condition. A similar procedure was used to alleviate interview anxiety in psychiatric patients (Bruch, 1975). Bruch's results were not as consistent as Meichenbaum's, but he did report improvement of subjective anxiety according to self-ratings among the coping subjects as compared with the mastery subjects. Working in the area of anxiety associated with surgery, Vernon (1974) reported that subjects who observed a model who showed some degree of pain were rated as experiencing less pain subsequently than were subjects who observed a model who did not demonstrate pain. Perhaps a study that fails to demonstrate effects is as important as affirmative studies. Lira, Nay, McCullough, and Etkin (1975) reported that adult female subjects who observed a fearless "expert" model were uninfluenced by that model as compared with a control group, based on behavioral and self-report measures. Meichenbaum (1971) acknowledged, however, that the greater effectiveness of the coping model in his study could have stemmed from the modeling of coping techniques that were an inherent feature of the coping conditions, rather than from the perceived similarity between observer and model per se. In consideration of this point, Kornhaber and Schroeder (1975) presented models who did not demonstrate deep breathing, which was central to Meichenbaum's coping model. With this confound removed, Kornhaber and Schroeder found greater change in evaluative attitudes toward snakes among those who observed a fearful model as compared with those who observed a fearless model, but they obtained no differences on a behavioral measure. Also, Jaffe and Carlson (1972) found no differences on behavioral and self-report measures of test anxiety between adults who observed a calm model and adults who observed an anxious model. These findings are generally consistent with Kornhaber and Schroeder's (1975) suggestion that with model coping skills removed, the greatest effect of a coping model may be on attitudes rather than on overt behavior.

A number of other researchers have adopted the Meichenbaum procedures in their applications of SM to clinical problems. The more focal problems of phobias and stress associated with dental and medical procedures

have been responsive to the coping manipulations. Lewis (1974) found water-phobic subjects to be significantly improved at the posttreatment assessment after they observed a coping model. Hill, Liebert, and Mott (1968) and Spiegler, Liebert, McMains, and Fernandez (1969) combined the mastery and coping procedures by depicting an "expert" model who demonstrated competent dog or snake handling to an initially apprehensive (i.e., coping) model. The second model then imitated the first model. Both research groups found moderate support for the combined modeling approaches, based on behavioral measures. In her studies of dental anxiety (Melamed, Hawes, Heiby, & Glick, 1975; Melamed, Weinstein, Hawes, & Katin-Borland, 1975) and anxiety associated with surgery (Melamed & Siegel, 1975), Melamed used coping models to successfully reduce the disruptive behavior of children undergoing these procedures. Except for Gottman (Gottman, 1977; Gottman, Gonso, & Schuler, 1976), who obtained weak effects, most studies have reported positive effects in using a coping model with interpersonal problems (Evers & Schwartz, 1973; Evers-Pasquale & Sherman, 1975; Jakibchuk & Smeriglio, 1976; O'Connor, 1969, 1972; Thelen et al., 1976).

Narration

Bandura (1977) has emphasized the importance of attentional and imaginal-verbal cognitive processes in modeling. In general, four subprocesses of modeling are emphasized by Bandura. In order to imitate, the observer must first attend to the critical model behavior. Second, the cognitive processes of imagery labeling and verbal labeling that are sustained over time by rehearsal facilitate later imitation of a model when external modeling cues are not present. Third, in order to overtly imitate a model, a person must have the motor reproduction abilities that are particularly relevant to more complex motor behavior. Last, although modeled behavior can be acquired by observation alone, reinforcement is critical if observed behavior is to be performed and this performance is to be continued over time.

Some aspects of the SM research reviewed in this article are relevant to these conceptualizations. One variable that has received considerable attention is narration, or a description of the model behavior concurrent with model performance. Based on current theorizing, narration should facilitate attention to the model and verbal labeling of the critical model behavior and thereby should increase the effectiveness of modeling interventions. Jakibchuk and Smeriglio (1976) reported that SM plus narration failed to significantly affect the social behavior of isolated preschool children in comparison with two control groups. However, researchers have reported that SM plus narration diminishes snake fears in adults (Spiegler et al., 1969), social isolation among preschoolers (Evers-Pasquale & Sherman, 1975; Keller & Carlson, 1974; O'Connor, 1969, 1972), and anesthesia fear among children (Vernon & Bailey, 1974). Since SM alone often has a favorable effect, it is of questionable value to demonstrate that SM plus narration has a favorable effect. Perhaps the greater question is whether narration has an incremental effect on SM alone. On this question Morris, Spiegler, & Liebert (1974) found that SM plus narration was equal to SM alone, based on a self-report measure of snake fear among adolescents. No other studies directly compared SM plus narration with SM alone.

Although the effect of adding narration to SM is uncertain, Jakibchuk and Smeriglio (1976) reported a timely study in which they compared narration with the influence of self-guiding model comments on the social isolation behavior of preschool children. They found that SM plus self-guiding comments by the model had a significant effect in comparison with two control conditions and in comparison with an SM plus narration condition. These findings are consistent with the earlier work of Meichenbaum (1971), who reported that a model's self-verbalization facilitated reduction of snake fear among female undergraduates. It may be that self-verbalization facilitates the conversion of the model's behavior into perceptual-cognitive images, as described by Bandura (1977). Perhaps model self-verbalizations are especially facilitative when the model behavior is relatively complex; however, there is little systematic research relevant to this point.

Context and Complexity of Model Behavior

The nature of the model context may be critical to attentional processes. It is suggested that the model context needs to be sufficiently simple to insure attention to the critical model behaviors, but it also should contain enough contextual cues to facilitate generalization to other settings. Furthermore, as the complexity of the target behavior increases, there may be greater need to both simplify and amplify the target behaviors. An example of such simplification of complex target behaviors is Hersen et al.'s (1973) reliance on eight response modalities characteristic of assertive responses. These included a lengthy reply, a request for behavior change, consistent eye contact, a refusal to comply with unreasonable requests, a fully audible speaking voice, an assertive affect, a quick latency of response, and overall assertiveness. Elaborative or focusing narration, self-guiding comments, or instructions may be used in conjunction with simplified target behavior to further increase the subject's attentiveness to relevant materials. By these means, the subject's attention is directed to the subtleties of the interpersonal interactions, which may otherwise go unnoticed in daily naturalistic modeling.

In the course of developing modeling films for interpersonal skills, it is important to avoid overwhelming the observer. Even with simplification and elaboration it is possible to overload the observer with too many significant points of focus. Burrs and Kapche (Note 1) failed to achieve successful results using SM with psychotic inpatients. In his criticism of their study, Goldstein (1973) cited their research as an attempt to cover too much ground in short videotapes. However, when combined with role playing, SM may be effective with more complex skills, for example, requesting new behavior, whereas instructions may be adequate for less complex skills, for example, eye contact (Eisler et al., 1973; Hersen et al., 1974; Hersen et al., 1973).

Uncertainty, Arousal, and Model Warmth

Other considerations are also very likely to be relevant to the matter of attention to and imitation of the model. For example, Yussen & Levy (1975) found that subjects who observed a warm live model attended to the model and recalled the model's behavior more than did subjects who observed a neutral live model. Others have suggested that uncertainty in the observer may increase attention to and subsequent imitation of a model (Marlatt, 1972; Thelen, Paul, Dollinger, & Roberts, 1978). If this is the case, it is likely that individuals will profit most from SM at those times when they actively seek information regarding appropriate behavior, for example, shortly before a stressful medical procedure. On the other hand, if an observer experiences extreme anxiety in anticipation of a stressful event or if the model's behavior creates a great deal of anxiety in the observer, the observer may avoid attending to the model.

Retention

As reflected in the methodologies of much of the SM research, especially in the failure to routinely collect data on maintenance, there is relatively little material relevant to the question of retention. The behavioral rehearsal and practice components that were so frequently used in the interpersonal skills research might be expected to facilitate not only immediate imitation of the model but also the retention of the modeled behavior (Bandura, 1977). However, there is no research that documents the influence of rehearsal and practice following observation of a symbolic model on the retention of behavior. Research by Thelen, Fryrear, and Rennie (1971) with a nonclinical target behavior (i.e., standards of self-reward) suggests that the influence of observing a model can have long-term effects.

Model Consequences

If shown to be useful, model consequences can easily be incorporated as part of SM. Also, model consequences have been extensively researched (Thelen & Rennie, 1972) and are important to the theorizing of Bandura (1977), who ascribed both informational and incentive functions to this variable. Many of the studies that focused on anxiety-related problems did not contain model consequences,

perhaps because of the assumption that the absence of negative consequences following the demonstration of the feared act in itself serves as positive model reinforcement. Model consequences were included in some of the studies on social isolation in preschoolers (Evers & Schwartz, 1973; Evers-Pasquale & Sherman, 1975; O'Connor, 1969, 1972), on assertion (McFall & Twentyman, 1973), and on dental and medical stress (Melamed, Hawes, Heiby, & Glick, 1975; Melamed, Weinstein, Hawes, & Katin-Borland, 1975). Although all of these studies showed some positive effects for SM, none of them manipulated the model-consequences variable. Therefore, this research does not establish that model consequences have an additive effect on the influence of SM alone.

Acquisition Versus Disinhibition

Yet another aspect of Bandura's (1977) theory of imitation is his distinction between two effects of modeling: disinhibition and the acquisition of behavior. A behavior that has previously been acquired may not be performed because of fear or anxiety. Observation of a model engaging in the behavior without negative consequences or with positive consequences may disinhibit the behavior or increase its frequency. New patterns or sequences of behavioral components also are exhibited by observers following observation of a model. In this manner novel behaviors are acquired.

It is potentially important to both application and theory to determine if SM primarily facilitates anxiety reduction and disinhibition or skills acquisition. Of course, it is possible that SM has an important influence in both areas. The treatment components that researchers have combined or compared with SM may give some clues as to their thinking regarding this matter. Research on the use of SM with phobias, test anxieties, and dental–medical stress used primarily relaxation and desensitization as additional components and as comparison treatments. One might infer that researchers see these problems as primarily involving anxiety and inhibition. In contrast, the components (e.g., rehearsal) used by most researchers of interpersonal problems reflect an assumption of a skills deficit. However, two recent studies raise the question as to the extent that skills deficits are the cause of some of the interpersonal problems studied. Schwartz and Gottman (1976) found that low-assertive college students were as able as moderate- and high-assertive college students to write out what they thought a good assertive response might be. Even more significantly, when asked to role play an assertive response for a hypothetical unassertive friend, the low-assertive students were as assertive as the moderate- and high-assertive students. Consistent with the above, Nietzel and Bernstein (1976) found that high-demand instructions made unassertive college students more assertive than did low-demand instructions. Both of the above studies suggest that assertive responses were in the behavioral repertoires of the low-assertive college students. However, since both studies were with college students, similar conclusions regarding other clinical populations are not possible. For example, it is likely that unassertive psychiatric inpatients have a more severe behavioral deficit than do unassertive college students (Hersen & Bellack, 1976).

Morris et al. (1974) have suggested that there are two components in phobia problems, one cognitive and the other emotional. The cognitive component involves information about alternative responses and expected outcomes that might ensue. The emotional aspect involves autonomic processes. Morris et al. suggested that the cognitive aspect should dominate in the anxiety of relatively normal subjects with snake fears because of their lack of experience and their faulty beliefs. They found that high school children with snake fears who observed a symbolic model showed more fear reduction than a control group, based on a cognitive (worry) measure but not on an emotionality (autonomic reactions) measure. Based on these findings, one might infer that SM is better suited to changing cognitive functioning and perhaps not so effective in changing autonomic processes. These findings are generally consistent with a study by Bandura and Menlove (1968), in which they showed that high-emotion-prone subjects in a multiple model condition showed less reduction in dog

fear than subjects who were not high-emotion-prone. Morris et al. worked with relatively normal subjects, who may be more similar to the moderate-emotion-prone subjects than to the high-emotion-prone subjects in the Bandura and Menlove study. One implication of these findings may be that SM is not as effective with more severe clinical problems that involve a strong anxiety component. Research is needed that addresses this question.

Multiple Models

Another facet of an SM treatment that is easily incorporated is the use of multiple models instead of the presentation of a single model. The purpose of using multiple models is to increase the odds that the observer will select at least one model to imitate, to provide multiple exposures to the target behavior, to increase the treatment stability, and to facilitate generalization of the behavior. Many of the studies reviewed in Table 1 employed multiple models, and this was especially likely in those studies that assessed generalization. However, only Bandura and Menlove (1968) actually manipulated the number of models. In their study the usual posttreatment, follow-up, and generalization comparisons failed to differentiate the dog-fearing children who observed multiple models from those who observed a single model. However, more children in the former group completed the behavioral approach test than did children in the single model group. Since the use of multiple models is readily incorporated in an SM treatment, and since multiple models logically seem to facilitate generalization, this question is clearly in need of research.

Length of Model Presentation

The length of the model presentation is another consideration that is potentially critical to the effectiveness of SM and on which the studies vary considerably. However, none of these studies systematically manipulated the length of the model presentation, and therefore little can be gleaned in this regard. A study by McGuire, Thelen, and Amolsch (1975) of self-disclosure showed that instructions were as effective as modeling when the audio model presentation was brief, but when the model presentation was longer, the audio model was more effective than were instructions. If SM is to become a treatment in general use, it is important to establish the optimal length of model presentation for various clinical problems and clinical populations.

Methodological Considerations

One could write an entire volume on methodological concerns in this area of research; only some of the more critical matters are discussed here. These points generally pertain to a number of studies rather than to one or two isolated studies. The following discussion concerns (a) subject selection, (b) defining the treatment or the independent variable, (c) control groups, (d) criterion measures of change, and (e) generalization and maintenance.

Subject Selection

No study can be better than the accuracy of the clinical population sampled. In the case of interpersonal skills problems, some researchers obtained subjects through psychology classes, which is probably not as desirable as obtaining subjects through newspaper advertisements (Little, Curran, & Gilbert, 1977). Psychology students are a relatively homogeneous population, and they are seldom completely naive concerning the experimental hypotheses. Inferences from studies that used college students to more diverse populations are highly risky. A strength in the research on dental–medical fears is that the subjects were drawn from the clinical setting in which the problem was demonstrated.

Another related problem is the tendency in SM research to use people who have relatively minor clinical problems. This is most apparent in the research on snake phobias. As Morris et al. (1974) suggested, the efficacy of SM with relatively normal snake phobics may not obtain when SM is applied to a more clinical population. There is a dire need for research on the effects of SM with more truly clinical and more disturbed populations.

Definition of the Independent Variable

The definition of the independent variable or the composition of the treatment is another

critical area. Although some of the studies compared SM alone with one or more control conditions, the prominent tendency, especially in the studies on interpersonal skills, has been to put SM with a basket of components. The net result is that one knows relatively little about the individual influence of SM as a separate component and relatively little about what SM might contribute to an intervention that contains one or more other components. Only a limited number of studies were designed to identify the influence of the specific components (cf. Goldstein et al., 1973; O'Connor, 1972).

Comparisons With Control Groups

If one wishes to attribute assessed changes to treatment variables, one must rule out the various effects that may be attributed to assessment, attention, placebo, or other demand characteristics. In general, the research on dental or medical stress and interpersonal skills controlled for the influence of assessment, attention, and placebo. But the research on phobias and test anxiety all too often contained only a no-treatment control, which does not allow one to rule out the influence of nontreatment variables. However, when the primary purpose of a study is to compare SM with other treatment techniques, an instruction/demand control may not be critical.

Many of the studies on interpersonal skills that used role playing (rehearsal) as part of the treatment package also used role playing to assess possible changes in interpersonal behavior, but did not control for practice in role playing. It is possible that any assessed changes in these studies stemmed from the increased competence of the treatment subjects at role playing, whether it pertained to assertiveness or to other behaviors. Therefore, if role playing is a part of the treatment and assessment, it is important to control for role playing as a general skill that can be learned.

Assessment

The matter of assessment in research on SM is both critical and complicated. A number of different methods have been used to assess the effect of the intervention, including self-report, physiological, and a variety of behavioral measures. Many researchers assessed behavioral changes in role-playing situations, whereas others assessed behavior by creating circumstances relevant to the behavior under investigation and unobtrusively observing the subjects' responses. Other behavioral measures that have been employed include direct observation in natural settings by trained observers and general ratings from informed acquaintances of the subjects.

Much of the research on SM contained a number of measures to assess the effects of the intervention, and most researchers in this area generally support the idea of multiple dependent measures. However, many researchers have pointed out the poor relationship between some of these dependent measures, as for example between behavioral and self-report measures of assertion (Rich & Schroeder, 1976) and of anxiety (Paul & Bernstein, 1973). Perusal of Table 1 reveals discrepant findings for relationships among the various dependent measures within a number of studies; that is, significant differences between groups were obtained on one type of measure (e.g., self-report) but not on another type (e.g., behavioral). Additionally, the large number of instances of mixed results on a given type of measure (as indicated by asterisks in Table 1) illustrates the frequent use of multiple behavioral and self-report measures. When a large number of measures are obtained, significant differences are more likely a function of chance.

A number of researchers have questioned the reliability and validity of the assessment methods used in SM research. For example, evidence has been presented indicating that the behavioral avoidance tests used to assess target anxiety in phobics are subject to a variety of uncontrolled situational and procedural influences (Bernstein & Nietzel, 1973). Bernstein and Nietzel argued that such influences as demand characteristics and instructional differences potentially obscure the relationship between treatment variables and anxiety. This is especially true when such influences result in the inclusion of less phobic subjects, who may respond more readily than

"true" phobics to posttreatment demands for approach behavior (Bernstein & Paul, 1971). Role-playing procedures used to assess assertiveness and heterosexual anxiety may be similarly influenced by instructionally mediated demand (Nietzel & Bernstein, 1976), thus limiting the validity of such procedures. The reliability and validity of most self-report measures of assertiveness have also been criticized (Rich & Schroeder, 1976), and such tests may be insensitive to treatment effects (see Table 1). Finally, Gottman (1977) criticized the naturalistic-observation assessment procedures employed in previous studies of SM with socially isolated preschoolers. These studies were criticized for the lack of detail in the coding systems employed, the failure to adequately control observer bias, the use of error-prone time sampling procedures, and the failure to control for interobserver reliability "decay" and observer "drift."

In summary, it seems to be important to incorporate multiple measures into an assessment of the effects of SM. However, there is a need for more serious consideration of assessment problems in future SM research. One last point deserves mention. Only three of the studies reviewed in Table 1 used a physiological measure to assess change. Even though there are problems with physiological measures, in that correlations between physiological measures are low and are sometimes inconvenient to obtain, greater use of such measures seems to be indicated. This would be especially true when treating anxiety-related problems and might eventually help to clarify the controversy concerning the relative roles of anxiety and skills deficit in the various areas studied.

Generalization and Maintenance

Since nearly all of this research, except that on dental and medical stress, was not carried out in a naturalistic setting, it is important to address the question of generalization. The second to last column in Table 1 demonstrates the relatively small percentage of studies that assessed generalization. And even some of the studies that assessed generalization did so in a way that leaves much to be desired. Recognizing that generalization is on a continuum, many of the researchers seem to have appraised generalization within a context that more closely approximated the treatment situation than the natural environment. For example, some of the phobia research appraised generalization by introducing a snake different from the one used for treatment. What does this tell us about the subject's response to a snake that they happen upon in their backyard on a Sunday afternoon? Similarly, a frequent method of assessing generalization in assertion research has been to introduce role-playing scenes that are different from those used for treatment. Surely this measure of generalization more closely approximates the treatment situation than the natural environment. The time has come to use generalization measures that appraise the subject's behavior outside the treatment setting and in settings more like the natural environment. The dental and medical research represents a clear exception to this problem. Since treatment and data collection typically occur within the natural environment, the question of generalization becomes less of a problem.

The question of maintenance has received about as little attention as generalization (see the last column of Table 1). When measures of the maintenance of effects were taken, they often were obtained within a few days after treatment. Even more critical is that these researchers typically did not assess the duration of the changes in the natural environment. In short, duration without generalization is of little value.

Conclusions

Based on the research reviewed in this article, it appears that the use of symbolic modeling as a treatment device, perhaps combined with other components, may have a promising future. If nothing else, the research to date suggests a great potential in this area. At this point, the need is for studies with more clinical or disturbed populations, for studies that systematically vary the treatment components, that carefully use multiple measures to assess change, and that appraise both generalization and maintenance in natural settings or in settings that closely approximate the natural environment.

This study examined 866 black–white employment test validity pairs from 39 studies for evidence of differential validity beyond that which would be expected on the basis of chance plus various statistical artifacts. The data in this study, unlike those in previous studies of differential validity, were free of Type I bias induced by data preselection. The results support the hypothesis that findings of apparent differential validity in samples are produced by the operation of chance and a number of statistical artifacts and indicate that true differential validity probably does not exist.

The question of whether traditional employment tests are appropriate for blacks and other minorities is an important one today. Researchers have approached this question from two different directions: from the point of view of subgroup validity differences and from the point of view of selection fairness. Although these two phenomena are related, they are by no means identical. For example, a test with equal subgroup validities can nevertheless be unfair, under certain circumstances, when used in selection. In earlier articles, we examined the properties of various models of test fairness (Hunter & Schmidt, 1976; Hunter, Schmidt, & Rauschenberger, 1977; Schmidt & Hunter, 1974). For other treatments of selection fairness, see Gross and Su (1975), Novick and Petersen (1976), and Cronbach (1976).

Differential and Single-Group Validity: Definitions and Research

Research in the area of subgroup validity differences has focused on two hypotheses: the single-group validity hypothesis and the differential validity hypothesis. The single-group validity hypothesis states that, for at least some tests, validity in the applicant population is zero for one group (e.g., blacks) but not for the other (e.g., whites), that is, $\rho_1 = 0 < \rho_2$. The research evidence against this hypothesis is now overwhelming (Hunter & Schmidt, 1978). Four different studies based on cumulative available research results (Boehm, 1977; Katzell & Dyer, 1977; O'Connor, Wexley, & Alexander, 1975; Schmidt, Berner, & Hunter, 1973) all found that the frequency of single-group validity does not exceed that which would occur by chance alone given equal population validities.

The differential validity hypothesis, on the other hand, is more general. It states merely that the validities in the two applicant populations are unequal, that is, $\rho_1 \neq \rho_2$. The status of this hypothesis is less certain than that of the single-group validity hypothesis. Because of small sample sizes and other problems, individual studies have limited statistical power to detect differential validity. Studies based on cumulative research results but focusing on the single-group validity hypothesis likewise have limited statistical power to detect differential validity and thus

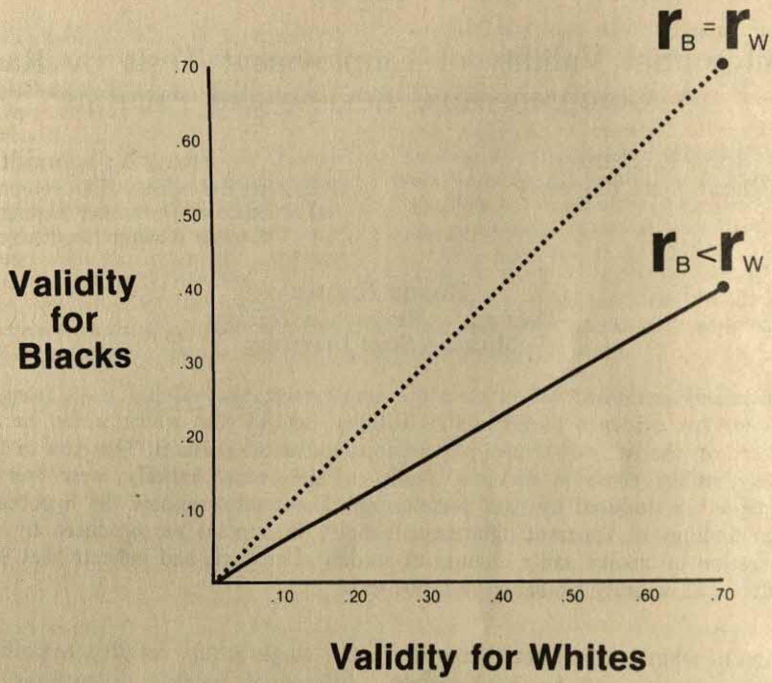

Figure 1. The level-based differential validity hypothesis ($r_B < r_W$) and the null hypothesis ($r_B = r_W$); B = blacks; W = whites.

provide only weak tests of the differential validity hypothesis (Hunter & Schmidt, 1978). Studies based on cumulative research results and focusing specifically on the differential validity hypothesis can have high statistical power for detecting differential validity. To date three such studies have examined the evidence for differential validity (Boehm, 1972; Boehm, 1977; Katzell & Dyer, 1977). However, these researchers preselected the data to be examined in such a way as to induce a massive Type I error bias in their results. Specifically, to be included in their analyses, at least one of the sample validities in a black–white validity pair had to be statistically significant. Hunter and Schmidt (1978) have shown that such preselection of data leads to the appearance of differential validity beyond chance levels even when there is in fact no differential validity in the parent populations. Thus the finding in these three studies that sample differential validity occurred in excess of chance frequency is difficult to interpret. A major purpose of this study is to examine the differential validity hypothesis using data that are not preselected.

It has been suggested (Boehm, 1972; Bray & Moses, 1972) that validity differences by race may be associated with the use of subjective criteria, such as ratings and rankings, and that such differences are infrequent when more objective criteria are employed. This hypothesis has found no support in connection with single-group validity. Schmidt et al. (1973) found that the frequency of single-group validity was at chance levels for both kinds of criteria. (The proportion of validity pairs showing single-group validity was significantly higher for subjective than for objective criterion measures [.37 vs. .20, $p < .001$], but this difference was predicted and fully explained by differences between the two data sets in individual sample sizes, differences between black and white sample sizes, and general level of test validity.) The second purpose of the present research is to test this hypothesis in connection with differential validity.

A third purpose of this research is to examine the differential validity hypothesis separately for different levels of validity. It may be that tests of generally low validity show little or no differential validity, while tests of higher validity show substantial differential

validity. This hypothesis is depicted graphically in Figure 1. This figure shows the predicted graph of test validity for blacks as a function of validity for whites. If a test is invalid for whites, it is predicted to be invalid for blacks also, and hence the function begins at the point (0, 0). The validity for blacks is predicted to increase as the validity for whites increases, but at a slower rate. Hence the function shown in Figure 1 is always less than the broken line, $r_B = r_W$ (B = black; W = white).

Although Figure 1 does illustrate the hypothesis that degree of differential validity is a function of level of test validity, the figure can be criticized in two respects. First, the comparison of the validity for whites and for blacks is made in the form of a comparison of the observed curve with the hypothetical broken line, $r_B = r_W$, rather than in the form of a direct comparison of curves for each group separately. Second, and more crucial, a plot of actual data (as opposed to population values) in the form of Figure 1 would show a definite bias produced by the sampling error in the correlations for whites. The sampling error in the white validity coefficients would function as an error of measurement in the independent variable in that it would result in a false reduction of the slope of the regression line; that is, a plot of real data would be biased in the direction of the differential validity hypothesis even if that hypothesis were false. This follows from the fact that measurement error (unreliability) in the independent variable—but not measurement error in the dependent variable—acts to attenuate the slope (cf. Hunter & Schmidt, 1976, for further development of this point).

An alternative manner of plotting the same hypothesis is shown in Figure 2. In Figure 2 the basic validity of the test is not defined as the validity for whites but as the average of the validity for whites and the validity for blacks. The separate validities for each group are then plotted as a function of the within-pair average, producing separate functions for whites and blacks. These two functions can then be compared in the usual way. First, if validity is zero for either group, then it is expected to be zero for the other group, that is, both functions start out at (0, 0). As the average validity for the test increases, the validity for each group increases. However, the validity for whites is expected to increase more rapidly than the validity for blacks, and

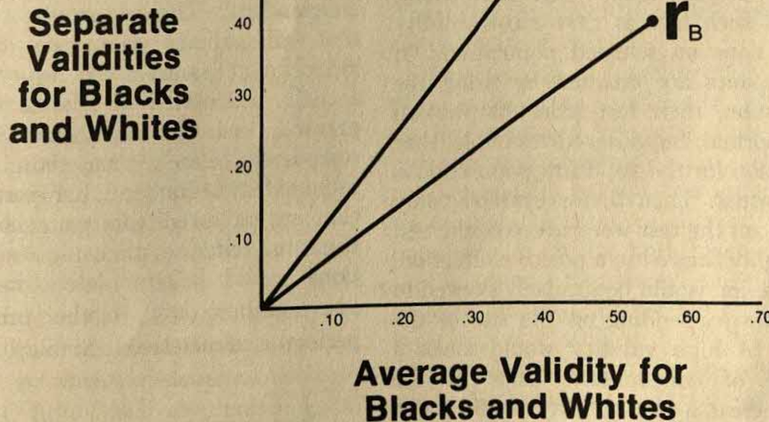

Figure 2. An alternate expression of the level-based differential validity hypothesis. (B = blacks; W = whites.)

hence the hypothesized curve for whites always lies above the hypothesized curve for blacks.

Data Analysis: Methods and Problems

A special form of chi-square test was developed for use in testing the differential validity hypothesis: The coefficients in each validity pair (r_B and r_W) are first transformed to Fisher's zs, that is, to z_B and z_W, respectively. For each validity pair, the chi-square is then as follows:

$$\chi^2 = \frac{(z_W - z_B)^2}{\dfrac{1}{N_W - 3} + \dfrac{1}{N_B - 3}},$$

where N_W is the sample size for whites and N_B is the sample size for blacks. Note that the right side of this equation is merely a squared Z score, as required by the definition of chi-square. The Z scores result, of course, from standardization of the validity differences after conversion of validities to Fisher's z form. For a single validity pair, this chi-square has only one degree of freedom, but (unlike a significance test between correlations) it can be cumulated over all pairs in a given range of average validity or over all pairs across all levels of validity to provide a test with high statistical power. However, because of the nature of the data that must be used in any study of differential validity findings from the literature, this chi-square test (and any other test) is characterized by a number of sources of Type I error bias.

Effects of nonnormality. The first factor that creates such bias is that most validity studies are done on selected populations. If such participants are selected by using the test in question, their test score distribution will be nonnormal. Suppose, for example, that the distribution for the applicant population is bivariate normal. Then if, for example, only the top 50% on the test were selected, the test would be highly skewed in a positive direction, and the criterion would be similarly skewed to a lesser extent, depending on the size of the correlation. (A high validity would mean a high degree of concomitant skew in the criterion, whereas a low validity would mean that the criterion would be approximately normal.) We found no literature examining the impact of these nonnormal distributions on the standard error of the correlation coefficient. However, we were able to derive a fairly good approximation. Our calculations show, for example, that for a 50% selection ratio and a validity of .5 in the applicant population (reasonable assumptions; see Schmidt & Hunter, 1977; Schmidt, Hunter, & Urry, 1976), the standard error of the selected sample validity coefficient is 8% larger than the full population standard error derived from the assumption of normality. The probability of finding a false reading of differential validity in such a situation is not the usual 5%, but rather 7%. (These calculations are available from the senior author.[1]) If such studies were added into a cumulative chi-square test, then each such study would add an expected increment of 1.16 to the chi-square, instead of the 1.00 that would be added if the full applicant population were sampled. This results, of course, in a Type I bias. In this study, we deal with a total of 866 black–white validity pairs. In the absence of Type I bias, the expected value of the cumulative chi-square over these validity pairs would be its degrees of freedom, 866. In the presence of this Type I bias, the expected value of the chi-square under the null hypothesis (that is, given the complete absence of any true differential validity) would be 1.16 (866), or 1,004.6 in our example, which would be deemed significant beyond the .0001 level.

Violations of independence. The second factor creating Type I error bias is the fact that not all validity pairs are statistically independent. The chi-square test assumes that all validity pairs are computed on independent samples. If several pairs are actually calculated on the same sample of persons (as is the case in nearly every study considered below), then those pairs are to some extent redundant. For example, suppose that several predictors were correlated with the same criterion; then the resulting correlations would be completely independent of one another only if the predictors were perfectly uncorrelated. Similarly, if one pre-

[1] These calculations are quite lengthy and are therefore not included here. They will, however, be presented in a future article.

dictor were correlated with several criterion measures, then the resulting correlations would be independent of one another only if the criterion measures were uncorrelated with each other. The effect of this partial redundancy produced by nonzero correlations between multiple predictors or between multiple criteria is difficult to calculate, and no attempt is made to correct for it below. Instead we simply state an example by way of warning. Suppose we had run a chi-square statistic over 100 validity pairs and had obtained an observed value of 128. Then, had those pairs been independent, we would have used the known facts about the chi-square distribution to conclude that the chance expected value of the chi-square statistic would be 100 and the standard deviation would be the square root of twice the degrees of freedom, that is, $\sqrt{(200)} = 14.14$, and hence an observed value of 128 would be significant at the 5% level. (Recall that a chi-square distribution with 100 degrees of freedom is essentially normal.) However, suppose we were told that an error had been made and that one of the numbers had been inadvertently written down 10 times. Then the expected value of the "chi-square" statistic would still be the nominal degrees of freedom, 100. To obtain the variance, we would note that this statistic was the sum of 91 independent entries, 90 of which had the usual chi-square variance of 2, whereas the last entry was repeated 10 times and hence had a variance of $10 \times 10 \times 2$, or 200. Thus, the true standard deviation would be $\sqrt{(180 + 200)} = 19.49$, and an observed value of 128 would no longer be statistically significant. Obviously, use of the smaller, erroneous standard deviation leads to a Type I error bias in the statistical test.

The typical correlation between alternate predictors and alternate criteria in the studies considered here is far less than 1.00. Thus the Type I error bias is probably not as great as in this hypothetical example. However, there is a Type I error bias. If in fact there is no true differential validity, the probability of rejecting this true null hypothesis is greater than .05; that is, when independence assumptions are not fully met, the nominal .05 alpha level is not the operational alpha level. The true alpha level is numerically larger, which biases the statistical test in favor of the alternate hypothesis that there is true differential validity.

When lack of independence is incomplete—which is usually the case—it is typically not possible to compute the correct standard deviation or degrees of freedom. If it were possible, the resultant chi-square statistic would of course not have a Type I error bias. However, this chi-square would have somewhat less statistical power than would be present if there were no violations of independence to begin with and the usual chi-square formulas were used to compute the standard deviation and the degrees of freedom.

Differential range restriction. The above two factors tend to produce the false appearance of differential validity by violating assumptions basic to the chi-square test. One other factor—differential range restriction by race—also tends to produce artifactual differential validity, although it does not violate strictly statistical assumptions. Such differential validity is artifactual in that it is produced by purely statistical factors that have nothing to do with substantive black–white cultural differences; that is, such apparent differential validity will manifest itself even when the validities of interest—the applicant population validities—are identical for blacks and whites.

The effect of range restriction on test validity was examined in detail by Schmidt et al. (1976). Suppose that the correlation in the applicant population is .50 but that only the top 40% of the applicants were selected and that the validity study was done on this group. The expected validity on the selected applicants would be only .31.

The situation is fundamentally more complicated when the validities of two groups are to be compared, because one must then consider the possibility that selection does not act equally on the two groups. Suppose, for example, that the validity in the applicant population is .50 for both blacks and whites; that is, suppose that there is no true differential validity. Suppose further that the cutoff score is set such that 40% of the whites are selected. The validity coefficient for the selected whites would be lowered to .31 by this artifactual restriction in range. Would the same happen to blacks? That depends on the mean black

test score. If the mean for blacks were the same as the mean for whites, then the effect of restriction in range would be the same. But this is typically not the case. Rather, there is usually a difference of about 1 standard deviation between whites and blacks on the test. If blacks have a test mean that is 1 standard deviation below the mean for whites, then the cutoff score is not .25 standard deviations above the black mean, as it is for whites; rather, it is 1.25 standard deviations above the black mean. Thus the selection ratio for blacks is not 40%, but 11%. Since blacks are much more severely selected, their test scores are much more severely restricted in range. In fact, the expected black validity is not .31, but .23; that is, selection at the same cutoff score for whites and blacks results in differential restriction in range and hence in an artifactual difference in the observed validities in the selected group.[2] The information necessary to correct validities for differential range restriction is rarely presented in studies.

Would an artifactual difference on the order of .30 versus .23 be significant in existing differential validity data? In the data reviewed for this study, the average Ns per validity pair were 140 for whites and 75 for blacks. If one considers a single study with these Ns, then this difference adds .231 to the chi-square (with 1 degree of freedom). This addition is nowhere near significant. Thus, this sort of artifact is not immediately detectable in single studies. But suppose that 866 such studies were run, as in this study. Then the chi-square pooled over the 866 validity pairs would be inflated beyond sampling error by 866 (.231) = 200; that is, the expected value of the chi-square would be 866 + 200 = 1,066. This would raise the probability of obtaining a significant cumulative chi-square from the 5% chance level prevailing when studies are done with applicant populations to the 99% prevailing when calculations are based on the selected applicants. [This calculation takes into account the fact that a noncentral chi-square has a larger standard deviation. For the central chi-square that represents the null hypothesis, the expected value would be its degrees of freedom, 866, and the standard deviation would be $[2(866)]^{\frac{1}{2}}$, or 41.64. For the noncentral chi-square, which represents the true state of nature here, the expected value would be 866 + .231 (866) = 1,066, and the standard deviation would be $\{[2+4(.231)]\, 866\}^{\frac{1}{2}} = 50.32$.] Had 866 separate chi-square tests been done, this same fact would have taken a different form. If the studies had been conducted on the applicant populations, then about 5% of the studies would have produced a false reading of significant differential validity. But in the selected applicant population, the probability of falsely detecting differential validity (i.e., the probability of a significant chi-square) is 7.5%. Over a large number of studies, this would lead one to falsely conclude that differential validity would be found in 2.5% (i.e., 7.5% minus 5.0%) of the corresponding job–test combinations.

Statistical power. In contrast to the situation prevailing with respect to Type I error biases, Type II errors are very well controlled in these data. Because the data set contains a large number of validity pairs (866) based on a much larger number of data points (see Discussion section), statistical power is very high. The probability of failing to detect true differential validity is quite low. Recall from our discussion of differential range restriction that the power to detect the small 7-point correlation difference between .23 and .30 is .99. Even for the trivial difference of .05 (Schmidt & Hunter, 1978), statistical power is .77.

In summary, the chi-square test used in this study was affected by three sources of Type I error. Obviously, the usual .05 level of significance was not appropriate for use with these data. In the case of the individual chi-square tests, for example, the expected percentage of tests significant under the null hypothesis (no true differential validity), using $\alpha = .05$, was not 5% but some substantially larger number. Based on the discussion above, it is our judgment that a conservative criterion would hold that findings of 10% or less disconfirm the differential validity hypoth-

---

[2] Even in unselected groups, tests scores of blacks have sometimes been found to be less variable (e.g., see Shuey, 1958). However, these findings have been based on school populations and may not apply to applicant populations.

esis and that proportions in the 5%–7% range constitute compelling evidence against the differential validity hypothesis.

A second test. In addition to the chi-square test, differences in mean validities between blacks and whites, within validity intervals and across all levels of validity, were examined using a critical ratio (*CR*) test. In this test, the error variance terms used were computed directly rather than being based on an assumed theoretical error distribution, as in the case of our chi-square test. This test can be represented as follows:

$$CR = \frac{E(r_W - r_B)}{SD_d/\sqrt{n-1}},$$

where the numerator is the average difference between the black and white validities, SD_d is the standard deviation of these differences, and n is the number of validity pairs. The advantage of this test is that departures from normality in test score or criterion distributions do not create Type I biases. The test is, however, affected by departures from independence and by differential range restriction. These effects operate to produce Type I biases of the same kind produced in our chi-square test, that is, the true alpha level will be numerically larger than the nominal alpha level.

Method

A careful review of published studies produced 39 studies reporting employment-test validities separately by race. These studies contained a total of 866 pairs of validity coefficients for which sample sizes were reported. A total of 532, or 61%, of the validity pairs were based on subjective criterion measures; 334, or 39%, were computed using objective criterion measures. These figures are shown by individual study in Table 1. All ratings, rankings, and so on, and grades in training (when not based on performance measures) were considered subjective criteria; performance measures such as quality and quantity of output, job sample measures of proficiency, errors, attendance, tenure, written job knowledge tests, and the like were considered objective criteria.

All coefficients were converted to Fisher's z, and values for the chi-square test described earlier were computed for each validity pair. The percentage of chi-square values reaching significance was calculated for (a) the overall group of 866 pairs, (b) each validity interval examined, and (c) the objective and subjective criterion measures. These chi-square values were also cumulated to produce overall values within each of these data categories. Critical ratios for level differences between blacks and whites were also run within each of these categories.

Results

The proportion of chi-square values significant at the .05 level in the total sample of 866 validity pairs was .09, which is less than our stipulated criterion of .10. The cumulative chi-square for the 866 pairs was 1,123.02, which is not significantly different from the value that might be produced artifactually given our earlier example of differential range restriction (1,066). Nonnormality of test and criterion distributions, induced by selection on the test, and violations of the independence assumption operated, of course, along with differential range restriction to bias the obtained chi-square of 1,123 in a Type I direction. Because of the large sample sizes, both these figures are nominally significant beyond the .01 level, but, as shown earlier, they are well within the range of results to be expected from Type I biases alone in the absence of any true differential validity. The overall mean racial difference in validity was .02 (whites higher). This difference, trivial from a practical point of view, is nominally statistically significant.

Figure 3 shows the results relevant to the hypothesis, which is illustrated in Figure 2, that degree of differential validity increases with level of validity. As the reader may recall from the discussion of Figure 2, the black and white validities (y-axis) are plotted separately as a function of the average of the two validities (x-axis). For positive validity, the curve is quite straightforward: There is no apparent evidence for differential validity. The only noticeable difference in the two curves is found in one point (the highest point) based on only 11 validity pairs, and for this point the mean black validity is higher than the mean white validity. On the other hand, the data for negative validities are strange and unexpected. All variables were either scored such that expected validity would be positive or were reflected to achieve the same effect. True negative validities were thus highly unlikely. Therefore, the negative correlations for both groups should represent sampling error, that is, negative deviations

from a population in which the correlation is close to zero. If this were true, then we would expect no differences between the curves for the negative validity samples. Thus, the observed difference (which is significant) suggests that something other than routine sampling error occurred in the negative validity samples.

The basic difference in the results for positive and negative validity samples was brought out by a second analysis: a count of the number of validity pairs that were significantly

different, that is, showed significant chi-square values. In the positive validity class, 45 out of 712 pairs were significantly different, that is, 6%, which is near even the nominal chance level. However, for the negative validity class, 32 out of 154 pairs were significantly different, that is 21%, which is considerably beyond the nominal chance level and perhaps even beyond the true chance level for these data.

A search of the data showed that the unexpected negative validities were concentrated in three studies: Farr, O'Leary, Pfeiffer, Goldstein, and Bartlett (Note 6), O'Leary, Farr, and Bartlett (Note 8), and Toole, Gavin, Murdy, and Sells (1972). The Farr et al. study contained 46 pairs of correlations; 23 of these were based on a sample of 31 black and 95 white clerical workers. In the group of 95 whites, only 5 of the validity coefficients were negative, and these were all near 0, ranging from $-.05$ to $-.10$. In the group of 31 blacks, all 23 coefficients were negative, and the average value was $-.24$. In this same study, another 23 validity pairs were based on a sample of 51 black and 158 white insurance workers. In the group of 158 whites, none of the validity coefficients was negative. In the group of 51 blacks, all but one coefficient was negative, and its value was .01. The average of the coefficients was $-.15$. In all cases, these validity coefficients were for types of tests that are valid in a positive direction in other black samples.

In one substudy of the O'Leary et al. study, 48 pairs of correlations were presented; 24 of these were based on a sample of 31 black and 60 white clerical machine operators. In the group of 60 whites, only 4 coefficients were negative, and all of these were near 0, ranging from $-.02$ to $-.07$. In the group of 31 blacks, 18 of the 24 coefficients were negative, and the average value was $-.21$. In this same study, another 24 validity pairs were based on a sample of 24 black and 106 white "miscellaneous" clerical workers. In the group of 106 whites, only 1 coefficient was

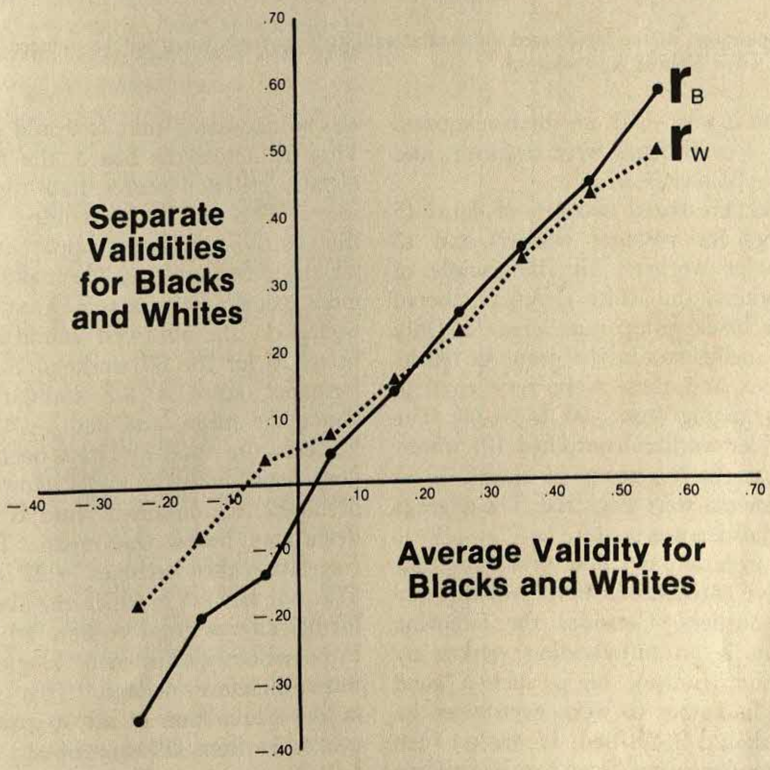

Figure 3. Graphic test of the level-based differential validity hypothesis based on all 866 validity pairs. (B = blacks; W = whites.)

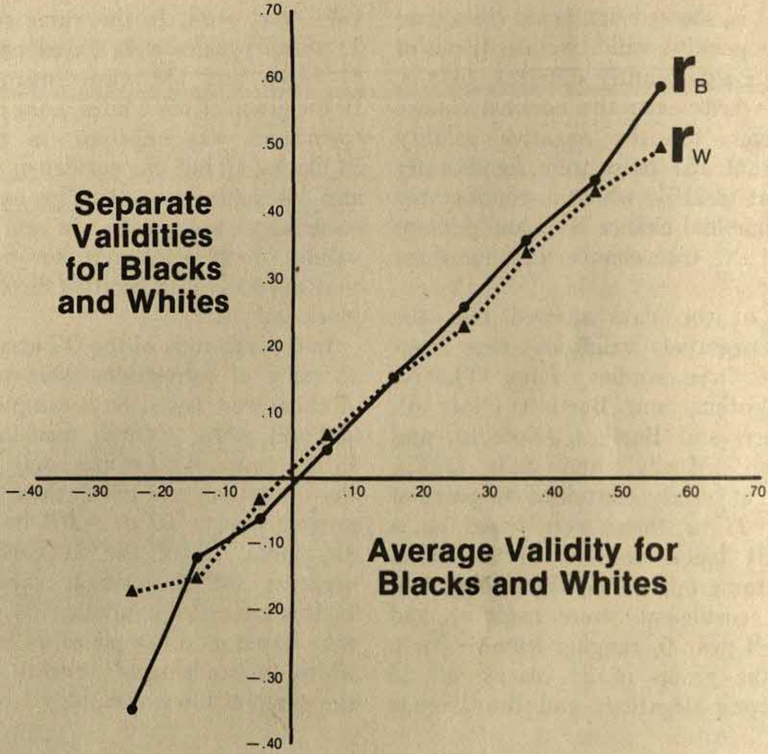

Figure 4. Graphic test of the level-based differential validity hypothesis based on the reduced data set of 781 validity pairs. (B = blacks; W = whites.)

negative, and it was −.01. In the black group of 24, only 2 coefficients were negative, and these were −.01 and −.07.

Toole et al. presented two sets of data: 15 validity pairs for younger workers and 15 pairs for older workers. In the sample of younger workers, the white group numbered 288 and the black group numbered 75. Only 4 of the 15 coefficients in the group of blacks were negative, and these were very small in magnitude, ranging from .00 to −.08. The sample of older workers contained 121 whites and 36 blacks. In the group of blacks, 13 of the 15 coefficients were negative. The average of the 15 validities was −.17.

Our interpretation of these results is that these negative correlations were probably the product of outliers. Consider the following parable. Sam is an outstanding worker by every criterion. Indeed, he is such a good worker that he comes to work even when he is sick and should be in bed. It was on such a day that the tests were given for the validity study. Sam did his best on the tests, but he was so nauseated that he could hardly think. Thus all across the board, the man with the highest criterion scores had the lowest test scores. This one outlier tended to cancel out the positive correlation apparent in the data for the other subjects. To make the example more specific, let us assume that had Sam not been sick, the observed validity would have been .20 for the 30 workers. Sam's job performance score is 2.5 standard deviations above the mean, and had he not been sick, his test score would also have been 2.5 standard deviations above the mean. However, because of illness, his obtained score is 2.5 standard deviations below the mean. The observed correlation then becomes −.22 instead of .20. The four samples in which the average validity for blacks was negative were all small enough to be seriously affected by single outliers and were therefore deleted. This step resulted in the elimination of all 46 pairs from Farr et al., 24 from O'Leary et al., and 15 pairs from Toole et al. In total, 85 validity pairs were dropped.

Figure 4 shows the comparison of black and white validity coefficients for the 781 pairs of validity coefficients remaining after the suspect data were deleted. The only point at which the curves differ noticeably is the highest point, which is based on only 11 pairs, and at this point the mean validity is higher for blacks than for whites. This figure clearly disconfirms the hypothesis that differential validity increases with validity level. Moreover, the two curves are now essentially equal for the negative validities resulting from sampling error, just as they are equal for the studies with positive validity.

The proportion of chi-square values significant at the .05 level was .067 in the reduced data set of 781 pairs. With 781 cases, the difference between 6.7% and 5% is nominally significant ($p < .05$, binominal test). But this small deviation from chance is in fact less than would be expected from the combined effects of the three known sources of Type I bias. The cumulative chi-square value was 874.4, which is nominally statistically significant ($p < .01$). But, again, the number of cases (781) is very large, and the result is actually miniscule when compared with that predicted from selection-induced skew in score distribution, violations of independence, and differential range restriction. In fact, the expected value of this chi-square in our earlier example of the range restriction artifact was 1.23 (781) = 961. The other two sources of Type I bias discussed earlier, of course, also operated here. The overall difference between the mean validities for whites and blacks was zero (to two digits), and the corresponding critical ratio was nowhere near significance ($CR = -.25$, $p < .60$). Thus these tests, taken together, suggest the absence of true differential validity in these data.

Table 2 shows the results of the three statistical tests separately for each level of average test validity. For example, in the validity category .51–.60, the mean validity for blacks is .58 and the mean validity for whites is .49. This mean difference is significant ($CR = 3.33$, $p < .002$) and leads to a significant chi-square, $\chi^2(11) = 23.80$. However, a check of the number of cases shows that for this validity interval, 2 of the 11 pairs are significantly different; a number this small could

[a] All data; none of the validity pairs dropped involved objective criteria.
[b] Data deleted as described in text.
[c] Negative values indicate higher white validities.
* $p < .05$ in absence of Type I biases; see text for discussion of these biases.

be due to chance. Evidence in this direction is found in the adjacent column for the validity interval .41–.50; here, despite containing nearly three times as many cases, the critical ratio is not significant.

The close comparability of mean black and white validities across the average validity intervals is particularly striking.[3] This fact is reflected in the values of the critical ratio assessing level differences in each of the validity intervals (last row of Table 2). Of the nine critical ratios, only two were statistically significant. One was the previously discussed validity interval .51–.60, which was based on only 11 validity pairs. In the other interval showing significance (.21–.30), the mean validity difference between blacks and whites (.26 − .23 = .03) was trivial in magnitude and was not replicated in the intervals on either side.

The proportion of validity pairs in which the difference was significant varied across the intervals from .00 to .18; the unweighted average was .087. Four of the nine cumulative chi-square statistics were nominally significant ($p < .05$).

In interpreting all the statistics in Table 2, one must again bear in mind the Type I biases that operated. In light of these biases, the statistics for validity intervals, like the whole-sample statistics discussed above, strongly suggest the absence of any true (population) differential validity.

Table 3 summarizes differential validity findings separately for objective and subjective criterion measures. These findings provide no evidence to support the hypothesis that differential validity is associated with subjective criterion measures. The overall proportion of significant chi-squares for subjective criteria was .10 in the complete data set and .06 in the reduced set. For objective criteria, the proportion was .08 in both data sets. Given the known sources of Type I bias in these data, all proportions must be considered in the chance range. Interestingly, the only cumulative chi-square that did not reach significance pertained to subjective criteria (reduced data set). The racial difference in mean validities appears to be negligible for both criterion types. To conserve space, the graphs of mean black and white validity values against average validity intervals are not shown separately for subjective and objective criteria. Both graphs for objective criteria are essentially identical to Figure 4. In the case of subjective criteria, the graph based on all data is very similar to Figure 3, and the reduced data set produces a graph essentially identical to Figure 4. Thus, the evidence appears to indicate that our overall conclusion about the nonviability of the differential validity hypothesis can safely be generalized across criterion types.

Discussion

The complete set of 866 validity pairs in this study reflects 185,487 data points (120,294 for whites and 65,193 for blacks). The reduced set of 781 validity pairs is based on 173,190 data points (111,333 for whites and 61,857 for blacks). Thus, statistical power in these

[3] The table computed on the unreduced set of 866 validity pairs is available from the authors.

analyses is almost infinite in comparison with usual research standards; that is, although Type I error biases are a problem in these data, there are no problems of Type II error biases. The probability of a Type II error, given even trivial validity differences, is close to zero. Yet no differences were found beyond those expected on the basis of Type I biases plus chance. In fact, the differences found were smaller than one might expect to find on the basis of the combined effect of these two factors. These results appear to clearly disconfirm the differential validity hypothesis. The conclusion must be that tests which rank order whites successfully with respect to some given criterion also rank order blacks equally successfully.

An argument occasionally heard against the earlier findings that single-group validity does not exceed chance frequencies may be offered in connection with the findings of this study. This argument can be summarized as follows. The frequency of differential validity does not exceed chance levels in the pooled data as a whole, and this finding does indicate that true differential validity is quite uncommon. But it may nevertheless be that specific instances of statistically significant validity differences observed in samples may reflect true differential validity in particular applicant populations. This argument must be addressed in terms of the overwhelming evidence. Recall that statistical power in this and similar studies is extremely high. If true differential validity existed in more than a tiny fraction of the applicant populations included in the study, it would be detected in the analysis of the data as a whole. Yet no such effect was observed in the data. The only possible conclusion, then, is that the probability is vanishingly small that any specific validity difference observed in samples reflects a true applicant population difference.

Some may object to the analyses performed on the reduced data set. In our judgment, the elimination of the 85 small-sample validity pairs (9.8% of all pairs) from the negative validity data set has been amply justified, but those who may disagree must still account for the fact that in the unreduced data set, the frequency of differential validity was clearly in the chance range (6%), even ignoring Type I biases, in the entire range of positive validities. Recall that all predictors were either scored such that expected validity was positive or were reflected to achieve the same effect. True negative validities (e.g., a negative population correlation between a cognitive ability and job performance), if they exist, must be regarded as anomalies. Clearly, most psychologists are essentially interested only in the positive validity range, and here the results for the complete and reduced data sets agree in strongly indicating the absence of any true differential validity.

What are the implications of these findings for the question of the appropriateness of personnel tests for blacks? As indicated earlier, lack of differential validity does not assure test fairness. For example, under the regression definition of selection fairness, regression line intercepts can be unequal even given equal validities and equal test and criterion variances. According to the regression definition of test fairness, such unequal intercepts denote unfairness to the group with the higher intercept when test scores are used in selection in the same regression equation for both groups. On the other hand, equal validities imply the impossibility of all of the forms of test unfairness specifically stemming from validity differences by race. For example, one potential cause of differences in regression slopes is differences in validity.

A more important point from a theoretical point of view, however, is that most substantive theories or hypotheses of test bias make predictions of differential validity (in addition to predictions of, for example, lower test means for blacks); that is, hypotheses of test bias have been based on the assumption that the actual content of tests, having been based on the content of white middle-class culture, does not mean the same thing psychologically to blacks as it does to whites. If this is in fact true, one result must be differential validity. Consider the following example. Suppose a certain perceptual speed test requires the examinee to follow complicated written directions. If there are differences in English dialect so strong that blacks must employ an internal translation process, two effects will result. First, blacks at a given level of ability in perceptual speed will have a more difficult

task than whites at the same ability levels and will make more errors, leading to lower test scores. Second, and more important, the factor composition of the test will not be the same for the two races. Whereas the test would assess only individual differences in perceptual speed for whites, it would, in addition, measure individual differences in internal translation abilities for blacks. The psychological meaning of the test scores will not be the same for blacks and whites, and thus the pattern of validities the test shows for various external criteria will differ by race. Thus, our failure to find any support for the phenomenon of differential validity in this study constitutes strong evidence against substantive hypotheses of test bias based on the assumption that the meaning of test content differs by race.

Unfair Discrimination in the Employment Interview: Legal and Psychological Aspects

Richard D. Arvey
University of Houston

The psychological and legal literature concerning evidence of bias or unfairness in the employment interview with regard to blacks, females, handicapped persons, and the elderly is reviewed. This review indicates that (a) the interview is highly vulnerable to legal attack and one can expect more future litigation in this area; (b) the mechanisms and processes that contribute to bias in the interview are not well specified by researchers; (c) findings based predominantly on resume research show that females tend to receive lower evaluations than males, but this varies as a function of job and other situational characteristics; (d) little evidence exists to confirm the notion that blacks are evaluated unfairly in interview contexts; (e) a relative dearth of research exists investigating interview bias against the elderly and handicapped individuals; and (f) evidence concerning the differential validity of the interview for these minority and nonminority groups is virtually nonexistent. A number of research needs and directions are specified.

Despite research that indicates that the employment interview has limited reliability and validity (Mayfield, 1964; Ulrich & Trumbo, 1965; Wright, 1969), organizational use of the interview in helping to make selection and promotion decisions persists. The statement of Dunnette and Bass (1963) that the personnel interview is the most widely used method of selecting employees still holds true today. In fact, there is some speculation that the employment interview may be gaining in popularity because of increased court and legal pressures brought to bear on employers' pencil-and-paper testing practices. In view of the increased likelihood of their employment tests' being subjected to legal scrutiny, employers are dropping the use of tests and placing even more reliance on the interview as the major decision-making tool.

An important but unsettling question remains, however, for those who abandon tests and adopt the interview for use in selecting and promoting employees. Does use of the interview result in unfair discrimination against protected minority group members? This question becomes even more important when one realizes that the interview is considered a *test* under the Equal Employment Opportunity Commission (1970) testing guidelines for selecting employees. Thus, the employment interview is (and has been) subjected to judicial review. Moreover, some recent evidence indicates that the interview process tends to yield judgments and evaluations about minority group members that make it less probable that they will be hired or promoted than that nonminority group members will be hired, even though the members of the two groups have substantially equal qualifications.

I intend to accomplish several objectives in the present article: First, I discuss various definitions of unfair discrimination in general and how components of these definitions apply to the employment interview; second,

---

This article is a greatly expanded version of a chapter in Arvey (1979).

I would like to thank Sheldon Zedeck for his review of earlier drafts of the article. A large portion of the research was completed while I was a visiting professor at University of California, Berkeley.

Requests for reprints should be sent to Richard D. Arvey, Department of Psychology, University of Houston, Central Campus, Houston, Texas 77004.

I review the legal literature and case law regarding unfair discrimination in the interview; third, I review the basic processes and mechanisms by which minority group members may come to receive lower evaluations based on the interview procedure; fourth, I review and summarize the research literature available concerning the evaluations given to minorities as a result of the interview process and whether these judgments exhibit differential validity in predicting job success; finally, I summarize trends and offer suggestions for future research efforts.

I selectively focus on the legal and research literature that concerns four basic minority groups: blacks, females, the elderly,[1] and the handicapped.[2] I have chosen to deal primarily with these particular groups because (a) the existing data base deals almost exclusively with these particular subgroups and (b) because the principles exemplified within the article generalize reasonably well to other subgroups.

Unfair Discrimination: Background and Definitions

As many of us are undoubtedly aware, Congress passed the Civil Rights Act in 1964, and Title VII of this act forbids discrimination against individuals in employment settings based on factors of race, national origin, religion, or sex. The agency charged with the interpretation and enforcement of this act was the Equal Employment Opportunity Commission (EEOC). In 1970 and again in 1978, this commission issued interpretative guidelines concerning the use and validation of employment tests in organization settings to insure the fairness of selection devices.[3] As mentioned, the employment interview was explicitly included under the rubric of tests and was subject to these same guidelines. Judicial definition of unfair discrimination gained greater precision in the now famous *Griggs* v. *Duke Power Company*[4] Supreme Court decision. In this decision, the Supreme Court ruled that the use of a general intelligence test and the use of a mechanical aptitude test were illegal because their use resulted in more whites than blacks being hired (adverse impact) and the test was not shown to be valid. The Court clearly enunciated a *shifting-burden-of-proof* principle, which applies to almost all litigation in this area today. First, an individual filing suit must demonstrate an adverse effect due to the use of a particular selection device.[5] For example, the finding that significantly more minority members than nonminority members were rejected for a position on the basis of an interview might be sufficient evidence to establish adverse impact. Subsequently, the burden of proof shifts to the employer, who must then establish the validity of the selection device. Since the interview is considered a form of test, the same two-pronged procedure is applicable. For an employment interview to be judged unfair, first, evidence would need to be presented that minority group members were evaluated more poorly than nonminority members on the basis of the interview and that these evaluations resulted in an adverse impact, and second, the employer would have to fail in establishing the validity of the interview.

It should be noted that another channel by which minority group members might challenge employment selection practices and the interview is by filing suits under the equal protection clauses of the Fifth and Fourteenth Amendments of the U.S. Constitution. Prior to 1975, suits filed under these authori-

---

[1] Individuals within the ages of 40 and 70 were extended protective coverage in the Age Discrimination in Employment Act of 1967 and recent amendments.

[2] Handicapped individuals were extended coverage by the Vocational Rehabilitation Act of 1973.

[3] In the past, other agencies (e.g., the Office of Federal Contract Compliance, Justice Department, etc.) issued separate testing guidelines. More recently, the various agencies jointly issued uniform guidelines on employee selection procedures (Equal Employment Opportunity Commission et al., 1978).

[4] Griggs v. Duke Power Company, 3 FEP 175 (1971).

[5] It should be noted that the more recent uniform guidelines stress that evidence for adverse impact should be assessed on the basis of the *total* selection process (the "bottom line" approach) in contrast with reviewing a single component of the process (i.e., the interview). It is not yet clear which reviewal process will be accepted by the courts.

ties were reviewed under the same standards as Title VII suits. However, in 1975, the Supreme Court ruled (in *Washington* v. *Davis*[6]) that when a suit is filed under these amendments, plaintiffs must demonstrate that the employer had an intent to discriminate (which is typically quite difficult to prove).

The 1970 EEOC guidelines call for the examination of whether a testing device (i.e., interview) exhibits the same pattern of validity for both majority and minority group candidates. Thus, an employer must determine that the interview is equally valid for both segments of the applicant pool. Employers are asked to determine whether their employment devices are *differentially valid* (Boehm, 1972). However, the more recent uniform guidelines (Equal Employment Opportunity Commission et al., 1978) indicate that instead of simply having researchers determine whether differential validity exists, studies of "fairness" should be carried out when feasible. One more sophisticated psychometric model of fairness calls for the investigation of regression line differences between majority and minority candidates (Cleary, 1968); that is, for the interview to be fair to minority and nonminority group members, the regression lines computed should be equal.

The more complex psychometric models of test fairness need not be presented fully here for the purposes of this article for two reasons: First, little agreement exists today concerning which of the more complex models of fairness is the most adequate model. Several relatively complex models have been advanced (Cole, 1973; Petersen & Novick, 1976; Thorndike, 1971) and are currently being evaluated and compared (Hunter & Schmidt, 1976). Second, research on interview fairness has simply failed to examine the issue from the perspective of these more sophisticated psychometric models, although it would be appropriate to do so.

To summarize, the fairness of the interview from a legal perspective can be evaluated from basically two perspectives: from the degree of adverse impact shown by interview judgments and from the degree of validity or job relatedness of the interview for majority and minority candidates.

Legal Aspects of the Interview

How has the employment interview fared when challenged in court by individuals claiming that they were discriminated against unfairly as a result of an interview? In almost all cases, the shifting-burden-of-proof standard is used. Cases in which the use of the interview in employment decisions has been challenged are shown in Table 1.

Perhaps the first and most often cited case in this area is *Rowe* v. *General Motors*,[7] decided by the Fifth Circuit Court of Appeals. The decision actually had to do with the performance appraisal used by the company in determining promotions, but because the case is used frequently as a controlling case, it is important to review it here. The decision dealt with the subjective nature of employment decisions, an obvious component of the interview. In this situation, foremen's subjective evaluations of hourly employees' ability, merit, and capacity were used in making promotion decisions. After determining that adverse impact had occurred regarding blacks, the court felt that the performance appraisal system violated Title VII in several ways: First, foremen were given no written instructions pertaining to the qualifications necessary for promotion; second, the standards that were determined to be in control were vague and subjective. In summarizing the decision, the court added that

> all we do today is recognize that promotion/transfer decisions which depend almost entirely upon the subjective evaluation and favorable recommendation of the immediate foreman are a ready mechanism for the discrimination against blacks, much of which can be covertly concealed. (*Rowe* v. *General Motors*, p. 450)

Thus, this decision casts some doubt on the employer's use of a subjective decision-making process if such a process resulted in adverse impact.

Table 1
Litigation Concerning Interviews

Case	Alleged discrimination against	Adverse impact shown	Validity of interview shown	Comment
Rowe v. General Motors (1972)	Blacks	Yes	No	Subjective standards said to be ready mechanism for discrimination
Equal Employment Opportunity Commission Decision No. 72-0703 (1971)	Blacks	Yes	No	Hiring system must permit review
Hester v. Southern Railway Company (1974)	Blacks and females	No		Interview noted to be subjective
United States v. Hazelwood School District (1976)[a]	Females	Yes	No	
Weiner v. County of Oakland (1976)	Females	Yes	No	
Harless v. Duck (1977)	Females	Yes	Yes	Interview successfully defended on the basis of content validity
King v. New Hampshire Department of Resources and Economic Development (1977)	Females	Yes	No	Questions in interview were indicative of discriminatory intent
Bannerman v. Department of Youth (1977)	Females	No		Adverse impact not shown

[a] Later appealed to the Supreme Court, but issues associated with the interview were not a part of this later decision.

In a 1971 decision,[8] the EEOC ruled that an employer's decision not to hire a black woman because of her "poor attitude" during the interview was in violation of Title VII. In this case, the EEOC cited a number of court decisions to establish that if discriminatory impact of a hiring system is shown, "it is essential that the system be objective in nature and be such as to permit review" (EEOC Decision No. 72-0703, p. 437).

The employment interview was also given court scrutiny in *Hester* v. *Southern Railway Company*.[9] A black female applicant was denied a clerical job partly as a result of the interview process. Although the district court ruled that an adverse impact had been demonstrated and that the interviewing procedure was faulty because of its subjective nature and because it was based on "no formal guidelines, standards and instructions," the court of appeals overturned the decision because there was no clear proof that these selection procedures (tests, interviews, etc.) had resulted in adverse impact.

A more recent case involved a court decision that struck down the use of the interview used in hiring teachers. In *United States* v. *Hazelwood School District*,[10] the court noted that the subjective interview process used in making selection decisions was similar to the vague and subjective criteria used in *Rowe* v. *General Motors*. It is instructive to read what the court said in this instance:

> Principals are free to give whatever weight they desire to subjective factors in making their hiring decisions. Indeed, one principal testified that interviewing an applicant was "like dating a girl, some of them impress you, some of them don't." . . . No evidence was presented which would indicate that any two principals apply the same criteria—objective and subjective—to evaluate applicants. (*United States* v. *Hazelwood School District*, p. 7576)

An interesting 1976 case (*Weiner* v. *County of Oakland*[11] dealt specifically with the kinds of questions asked in the interview and their possible bias. Mrs. Weiner applied for the position of intermediate planner and was given an oral interview that apparently was scored in some systematic way. Although Mrs. Weiner was ranked third on the list of eligible applicants, four men were hired to fill the available positions. As grounds for not hiring Mrs. Weiner, the county was only able to suggest some doubt about the flexibility of her approach to planning.

The court ruled that Mr. Weiner had demonstrated an adverse impact. At this point, the burden of proof shifted to the county, which had to prove that it had valid business requirements justifying its conduct. The county attempted to defend the use of the interview by asserting that the decision reached was based on subjective evaluations made during the interview that were in no way the product of sex discrimination.

The court, however, reviewed the kinds of questions that were asked of Mrs. Weiner and found that they were suggestive of bias against women. Questions such as whether her husband approved of her working, whether her family would suffer if she were not home to prepare dinner, and whether she was able to work compatibly with young, aggressive men were asked. The court ruled that these kinds of questions during the interview, along with other facts, were sufficient to substantiate the charge of discrimination and awarded back pay and attorney's fees.

A recent case provided sufficient evidence to the court regarding the interview to survive challenge. *Harless* v. *Duck*[12] involved a situation in which a woman brought a class action suit against a midwestern police department charged with discrimination in hiring because of sex. The department used, along with several other tests, a structured oral interview that consisted of approximately 30 questions posed to each candidate by a team of interviewers. The questions were designed to determine an "applicant's communication skills, decision-making and problem-solving skills, and reactions to stress

[12] Harless v. Duck, 14 FEP 1616 (1977).

situations." It was determined that 43% of the females failed the oral interview, compared with 15% of the males. After some discussion of proper sample sizes for detecting significant differences, the court determined that the discrepancy in pass rates was significant and that the interview did indeed have a discriminatory or adverse effect. In defending the validity of the interview, the organization relied on two sources of evidence:

1. The oral interview had construct and content validity. The expert witness for the organization testified that the structured oral interview portions of the exam, which consisted of hypothetical questions simulating situations likely to be encountered by patrolmen, measured several dimensions identified through job analysis that differentiate among persons who would be better patrol officers if put in a position to perform patrol functions.

2. A significant relationship between performance in the interview and performance at the police academy was shown. A previous Supreme Court decision (*Washington* v. *Davis;* see Footnote 6) had affirmed the use of measures of training success as legitimate criteria against which to validate a selection instrument. The court found this evidence sufficient to demonstrate the validity of the interview.

Another recent case is *King* v. *New Hampshire Department of Resources and Economic Development,*[13] in which a court of appeals found that the questions asked of a female who applied for the job of a state meter patrol officer helped to establish that discriminatory intent had occurred. In this instance, a female applicant was asked "whether she could wield a sledge hammer, whether she had any construction industry experience, and whether she could 'run somebody in'" (p. 670), none of which were related to the job in question. The court indicated that the employer's discriminatory intent was proved largely by its own words and actions.

Finally, in *Bannerman* v. *Department of Youth Authority*[14] the use of a panel interview was challenged. Candidates applying for a parole agent job were interviewed by a panel of three interviewers who were asked to judge each candidate in relation to stated "critical class requirements" (e.g., demonstrated ability to relate to youths and to gain their respect and confidence). However, the plaintiffs were not able to demonstrate to the satisfaction of the court any discriminatory bias against women; that is, there was no statistically significant difference between the pass rates of the males and females interviewed by the panel.

It is somewhat surprising that more cases dealing with interviews have not been litigated. It seems apparent that one direction in which the courts are moving is toward the exploration of the nature of and kinds of questions asked and the information elicited in the interview in more depth; that is, the content of the interview is being more fully examined. For example, inquiries during the interview that might convey to the applicant the impression that persons in a protected class will be discriminated against will now be viewed as discriminatory. In one case (cited in Babcock, Freedman, Norton, & Ross, 1975), the EEOC and the New York Human Rights Commission concluded that a New York law firm had violated Title VII when interviewers emphasized to female applicants that the firm had only one female lawyer and that she was assigned to an area of work traditionally performed by women. The conclusion was that "the interviews are conducted in such a manner as to express a preference for men and to discourage women from pursuing employment with respondent firm" (Babcock et al., 1975, p. 380).

Among these same lines, the specific kinds of information elicited on application forms and during interviews are being litigated. Managers are currently confused about what they may or may not ask during an interview. Although I do not provide a review of these more specific interview inquiries, it should be noted that litigation revolves around two basic themes:

---

[13] King v. New Hampshire Department of Resources and Economic Development, 15 FEP 669 (1977).

[14] Bannerman v. Department of Youth Authority, 17 FEP 820 (1977).

1. Do particular kinds of questions convey an impression of an underlying discriminatory attitude or intent? That is, references to "girls" and inquiries into non-job-related areas such as marital status, parenthood, child care, and so on, when these same questions are not presented to male candidates, may be sufficient to convince a court that discriminatory animus or intent is operating.

2. Does the inquiry operate in a way that demonstrates a differential impact or adverse effect on protected groups? If so, is the particular information valid or job related? Thus, organizations should avoid interview questions that operate in such a way as to differentially affect minority groups, unless such questions are job related.

Guidelines concerning preemployment inquiries have been set forth by a variety of state human rights commissions as well as by a set of guidelines issued by the EEOC. For example, the Washington State Human Rights Commission (1979, pp. 2923–2926) stated the following to be unfair and illegal preemployment inquiries when they cannot be shown to be job related: (a) all inquiries related to arrests; (b) any inquiry concerning citizenship; (c) specific inquiries concerning spouse, spouse's employment or salary, children, child care arrangements, or dependents; (d) overgeneral inquiries (e.g., "Do you have any handicaps?"—which would tend to divulge handicaps or health conditions that do not relate to fitness to perform the job); (e) whether the applicant is married, single, divorced, engaged, widowed, or any other inquiry as to marital status; (f) type or condition of military discharge; (g) any questions related to pregnancy; and (h) whether applicant owns or rents a home.

To summarize, although there have not been an overwhelming number of lawsuits involving the discriminatory nature of the employment interview, the litigation that has evolved clearly indicates that the interview is vulnerable to such suits. Interviews will indeed be treated like tests and reviewed by these same standards. I predict a greater number of suits in this area during future years. Organizations may find themselves even more ill equipped to defend the interview because of the little attention paid to quantifying interview judgments or conducting research to determine the reliability, validity, or adverse effects of the interview process.

Processes Inherent in Interview That Potentially Contribute to Differential Evaluation

The interview process is highly subjective. Schmidt (1976) has summarized a myriad of factors that contribute to interviewers' judgments and evaluations. Because of its basic subjective nature, the interview process is vulnerable to the personal biases, prejudices, and stereotypes of interviewers, thus making it open to challenge from civil rights litigants. Interviewers may form poorer evaluations of minority group members than of nonminority candidates, even when the candidates are substantially similar with regard to their job qualifications. Just how or why these differential evaluations are made is not well-known. There do appear to be two possible mechanisms that contribute to differential evaluations: (a) stereotyping and (b) differential behavior emitted during the interview.

Stereotyping

Decisions that are made on the basis of the interview are generally subjective in nature and thus susceptible, according to some individuals, to the influence of stereotypes. However, Brigham (1971) indicated that there is a good deal of confusion concerning the precise definition of stereotypes and their correlates. Most definitions (e.g., Lippman, 1922) revolve around the notion that stereotyping involves making judgments about people on the basis of their membership in a particular group. Once an individual's membership in a particular class or category is established (e.g., race, sex, age, etc.), a number of trait characteristics are ascribed to the individual based on the traits associated with the larger class of which he or she is a member. Thus, stereotyping involves basically two processes: (a) the for-

mation of impressions and trait descriptions of particular classes and categories of individuals and (b) the assignment of these traits to a particular individual once his or her membership in that class or category is known.

For example, Rosen and Jerdee (1976a) indicated that common stereotypes ascribed to males include such trait descriptions as adventurous, competitive, objective, dominant, decisive, and rough, whereas females are commonly described as compassionate, dependent, submissive, emotional, and so forth.

While many researchers have characterized stereotypes as the product of a rigid and faulty reasoning process that operates to help individuals rationalize and justify their hostility and prejudices, Brigham (1971) and Hamilton (1976) have suggested that stereotypes are not unlike other normal cognitive functioning processes. Hamilton indicated that stereotypes are "unfounded overgeneralizations," in that the perceiver does not use the available information in an optimal manner and bases his or her conclusions about a particular social group on poor evidence. In a similar vein, Katz (1960) has delineated several useful functions that stereotypes fulfill for different people (instrumental, ego-defense, value-expressive, and order functions).

It is interesting to note that although the notion of stereotyping is frequently invoked to explain why differential evaluations occur during interviews, the precise nature of how stereotypes operate and produce these different evalutions is not well specified. There appear to be at least three lines of speculation concerning this process. First, the stereotypes or trait characterizations may be essentially negative in nature; that is, the traits ascribed to a minority group and individuals from that group may consist of basically negative tones (e.g., blacks are dirty, uneducated, unintelligent, etc.). Thus, essentially negative attitudes and opinions concerning particular minority groups may have their basis in these stereotypic characterizations. Individuals holding essentially negative opinions and attitudes toward minority group members might be expected to give lower evaluations in an interview because of these attitudes. For example, Terborg and Ilgen (1975) found that attitudes toward women correlated significantly with a subject's decision to hire a female engineer. Individuals with essentially negative attitudes about women were less likely to give favorable evaluations than were those with more positive attitudes.

Similarly, Britton and Thomas (1973) gathered opinion data from 56 employment interviewers and found that they ranked older individuals as more difficult to place and train and as more slow in maintaining production. In addition, females were seen as more likely to be absent from work and as less skilled than men. Finally, older women were viewed as having fewer saleable skills than older men, but younger men and women (aged 18 years) were seen as having basically the same saleable skills. These negative opinions may lead to lower evaluations of older individuals and women in interview situations.

A second and more indirect manner by which stereotypes may affect interview evaluations is based on the process of matching the stereotypic traits with the characteristics thought to be necessary to perform the job. If a relatively poor match results, an interviewer may reject the candidate outright or give lower evaluations. Note that this process does not necessarily imply that the stereotypic traits are negative—indeed, they may even be positive in nature. Evaluations are potentially inaccurate (a) because of the inaccuracy of the stereotypes attributed to the individual, (b) because of the inaccuracy of the characteristics deemed necessary to perform the job, or (c) because the matching process itself is a poor decision strategy.

The research conducted by Schein (1973, 1975) is particularly representative of this second viewpoint. Schein (1973) asked 300 male managers to indicate which of 92 adjectives best described (a) women in general, (b) men in general, or (c) successful middle managers (each manager described only one of these three subgroups). She found that the relationship between the average descriptions of the middle manager

and the average description of the males was much higher ($r = .62$) than the relationship between the descriptions of the managers and of the females ($r = .06$). In fact, on 60 of the 92 items, the descriptions of the managers were more similar to the descriptions given to men than to the descriptions given to women. These findings suggest that even before an interview or any formal selection process has begun, the perceived similarity between the characteristics of successful managers and of men in general increases the probability of a male's rather than a female's being given a higher evaluation. These results were also replicated with a group of 167 female managers who also described the various subgroups (Schein, 1975). In this study, 167 female middle managers rated women in general, men in general, or successful middle managers on the same 92 adjectives. Like the male managers in the previous study, the female managers provided descriptions of successful middle managers that were far more similar to descriptions of men than to descriptions of women. The results suggest that female managers are as likely as male managers to accept stereotypical male characteristics as the basis for success in management.

A third manner by which stereotypes possibly operate is to shape the kinds of expectations and standards that interviewers have of job candidates during the interview. For example, it may be that an interviewer, after learning that the person to be interviewed next is female, evaluates the candidate on a different set of criteria—for example, beauty, typing skills, poise, and so on—than used for evaluating a male candidate. A study by Cecil, Paul, and Olins (1973) attempted to identify the qualities perceived to be important for male and female applicants for the same job. Over 100 subjects indicated the importance of each of 50 variables (e.g., pleasant voice, expressive self-will, etc.) to interviewers evaluating either a male or a female job candidate.

The results indicated that the kinds of standards and criteria used to evaluate the candidates depend on whether an applicant is male or female. The standards used to evaluate females are more clerical and cosmetic in nature, whereas the standards for males are along aggressive and persuasive dimensions.

Stereotypes obviously are also associated with race. Despite the Civil Rights Act of 1964, stereotyping of blacks persists today. For example, Karlins, Coffman, and Walters (1969) compared the racial stereotypes of undergraduate students in 1967 with the stereotypes reported in 1933 and 1951. Subjects in all three studies indicated those traits thought to be typical of blacks. Although the data indicated a consistent trend over the 25-year period toward giving more favorable characterizations of blacks, a considerable amount of stereotyping still exists. The students in the study described blacks as lazy, superstitious, musical, ostentatious, and pleasure loving. Considerably more information concerning the nature of racial and ethnic stereotypes can be found in Jones (1972) and Brigham (1971).

The nature of age stereotypes and how they relate to the job have recently received some research attention. Rosen and Jerdee (1976c) asked over 100 business students and realtors to imagine that they were going to meet two individuals for the first time and that the only information they had about the two people was that one was 30 years old and the other 60 years old. The participants in the study then considered 65 characteristics and indicated the degree to which each characteristic described the average 60-year-old male and the average 30-year-old male. Significant differences were found on several characteristics and are summarized as follows: The 30-year-old male was described as significantly more productive, efficient, and motivated, more capable of working under pressure, more ambitious, eager, and future oriented, more receptive to new ideas, more adaptable, and more versatile. The 60-year-old male was described as significantly more accident prone and more rigid and dogmatic.

Clearly the traits and characteristics ascribed to the older group are not particularly favorable. Rosen and Jerdee (1976c) noted that these stereotypes are also not consistent with objective research findings and

changes associated with aging (Schaie, 1974).

To summarize, the specific nature of stereotypes that interviewers hold concerning different minority groups may well influence their evaluations of these candidates during the interview process. To the extent that the stereotypes are basically negative, deviate from the perception of what is needed for the job, or translate into different expectations and standards of evaluation for minority group members, stereotypes may well have the effect of lowering the evaluations of interviewers, even when the candidates are equally qualified for the job.

Terborg (1977) has sounded a warning against the too quick acceptance of the notion that the pervasive effects of stereotypes explain or account for all differences in treatment by men and women managers. He suggested alternative explanations that may account for apparent discrimination. One alternative he posed is that many women are truly not yet qualified for managerial positions: "This is not meant to suggest that women lack potential for the job, but that the cumulative effects of past discrimination have prevented women from gaining the necessary skills and experience" (Terborg, 1977, p. 649).

Differential Behavior of Interviewers

One additional explanation for different evaluations of minority group candidates as a result of interviews is that minority applicants may behave in a manner that seems different and unfamiliar to interviewers. Hall (1966) specifically argued that subcultural differences in nonverbal behavior have resulted in whites' misreading of black applicants and therefore in blacks' failure to get jobs; that is, it is possible that blacks emit verbal and nonverbal behaviors (e.g., jive talk) that are acceptable and even desirable in their subculture, but that these same behaviors are misinterpreted or confused by a white interviewer. An interesting study was conducted in this regard by Fugita, Wexley, and Hillery (1974). White and black (20 of each) female undergraduate students were asked to participate in an employment interview. Acting as the interviewers were 2 black and 2 white males; eight questions were asked of the interviewees. Results of the study showed that the black interviewees maintained significantly less eye contact with both white and black interviewers. The least amount of visual interaction occurred when a black interviewee was interviewed by a black. Black interviewers were also given shorter glances than were white interviewers by both black and white interviewees. In sum, the race of the interviewee and of the interviewer appeared to be significant factors in the kind and amount of behavior that occurred during the interview. What would have also been of great interest is whether these differences in behavior also produced differences in evaluations by the interviewers.

It is possible that women, older workers, and handicapped individuals also differ in their reactions during interviews, which could contribute to lower evaluations. For example, older job candidates may be more thoughtful and cautious in their interview responses than are younger candidates. Sterrett (1978) conducted a study in which 100 male and 60 female managers evaluated videotapes of a male applicant in which the intensity of nonverbal body cues was manipulated. Results indicated that the male and female interviewers reacted significantly differently to the different kinds of body language.

Research Findings Concerning Different Evaluations in the Employment Interview

In the previous section, it was learned that one component of unfair discrimination from a legal perspective is whether the evaluations stemming from the interview result in an adverse impact on protected groups. In the present section, the various research studies that have investigated whether equally qualified minority group members receive lower evaluations on the basis of interviews are reviewed. These studies have generally employed one of three kinds of research strategies.

Resume Studies

In this kind of study, subjects (students, managers, recruiters, etc.) are asked to review a series of job resumes and to determine the suitability of each of the candidates for employment and/or the starting wage that might be offered. Each resume usually contains information about educational background and past experience, with a glossy photograph attached. In the typical study, the race, sex, age, or handicapped status of the job candidates can be manipulated through the photograph and the name, which is also printed on each resume. Thus, half the interviewers might be asked to make evaluations concerning, for example, five males and five females. The other half of the interviewers might be asked to evaluate five males and five females, with the only change being that the names and photographs are switched so that no change whatsoever occurs with regard to the qualifications of the candidates; the only changes made are in regard to sex, race, and so on. Obviously, the interviewers are unaware that the resumes they are evaluating may differ from those being evaluated by other interviewers. In addition, some studies have added several other variables such as applicant attractiveness, type of job, and so forth to determine if these characteristics may interact somehow with minority status and thus influence the evaluations given.

Another strategy researchers use is to have subjects evaluate and rate several resumes that vary by sex, race, and so on. Care is taken to equate the resumes with relevant characteristics other than the variables studied. One potential problem, then, with this within-subject design is the degree to which potentially confounding variables are effectively controlled.

Because many of the studies in this area use this resume approach, they obviously do not involve face-to-face interviews with real people. Instead, subjects are asked to evaluate "pencil-and-paper" people for jobs in organizations that are often not well described. One must infer that any discriminatory effects found in these studies generalize to actual interview circumstances.

"In-Basket" Study

In this design, participants in the study (students, managers, etc.) are asked to assume the role of a personnel director or manager who works through an "in-basket" and must take action and react to a number of items in memorandum or letter form. Typically, each in-basket provides information about the various departments in the organization and information about the members of the organization (e.g., performance appraisal data, attendance information, etc.). Also contained in each participant's in-basket are a series of different types of personnel problems. The participants are asked to make some kind of decision based on the information given. One of the decisions presented is the hiring or promotion of a particular individual. The problems are written in two or more versions so as to change the sex, race, age, and so on of one or more of the characters in the problem. For example, one participant may receive an in-basket set in which the problems involve whether a male should be hired or promoted, whereas another participant may receive the exact same information, except that the sex of the person being considered for hire or promotion is female.

Other kinds of problems are presented in addition to hiring and promotion. For example, training and development opportunities, leaves of absences, job assignments, and so forth are investigated with regard to whether participants make different kinds of decisions based on the sex, race, and so on of the individuals depicted in the in-basket materials.

Videotape Studies or Field Experiments

Less frequent studies employ designs in which actual minority and nonminority interviewees are observed by interviewers either face to face or in videotape presentations. Typically, interviewers (subjects, managers, etc.) interview or observe only one job candidate, who is either a minority or a nonminority member, and make evaluations about the suitability of the candidate for hire. Efforts are made to control the content

of the interview to insure that the same questions are asked and that similar responses are delivered by the interviewees.

Table 2 summarizes the results of 23 studies that have investigated bias in the interview. As can be seen, most studies employed the resume approach, the second most frequent strategy was the in-basket strategy, and finally, the videotape or in vivo type of study was used in only three instances. Although there is considerable variability in the sample sizes used across the various studies, the majority of designs (19) included more than 75 subjects. Thus, the studies were in general reasonably powerful with regard to detecting significance (Hayes, 1973).

Applicant Sex

The studies in Table 2 show in a reasonably consistent fashion that females are generally given lower evaluations than males where these candidates have similar or identical qualifications.

Dipboye, Fromkin, and Wiback (1975) gave 30 male professional interviewers and 30 male undergraduates 12 resumes to evaluate and rate for the position of head of a furniture department. Applicants' sex, physical attractiveness, and scholastic performance were manipulated. Among other findings, a main effect ($F = 15.84$, $p < .01$) for applicant sex was found in which male applicants were evaluated higher than were female applicants. However, this effect accounted for only 1% of the rating variance. One potential confound in this study was that the description of the furniture department job included several references to "him," which perhaps connoted to subjects that male applicants were preferred.

Dipboye, Arvey, and Terpstra (1977) provided a partial replication and extension of the aforementioned study. College students ($N = 110$) evaluated 12 resumes for a management-trainee sales position. Besides the qualifications of the ratees, subjects' sex and attractiveness were investigated. In addition to other findings (summarized below), applicant sex demonstrated a significant main effect on an employability rating. Raters expressed significantly more willingness to hire a male than to hire a female applicant ($F = 20.44$, $p < .001$). Again, however, this effect accounted for a minute proportion of the variance in ratings (.006).

Haefner (1977) asked 286 managers to rate 16 resume profiles in which applicant characteristics varied by sex, age, race, and competence. All applicants were described as being disadvantaged. In addition to several interactions (discussed below), sex exhibited a significant main effect ($F = 78.53$, $p < .01$) in which males were given higher recommendations for hire than were females. A factor that might have influenced the results of the study is that the presentation of the stimulus profiles and subsequent evaluations took place over the telephone. The effects, if any, of using this data collection procedure are not known.

Rosen and Jerdee (1974a) used 235 male undergraduate subjects to evaluate male or female candidates for jobs with demanding versus routine job requirements. Females were rated significantly lower than were males on an overall rating ($F = 14.02$, $p < .01$).

Zikmund, Hitt, and Pickens (1978) varied sex and scholastic performance of applicants in a resume study in which 100 personnel directors were asked to reply to letters from the candidates that expressed interest in an accounting job. The dependent variable was the number of replies received. Females received a significantly lower number of replies ($\chi^2 = 4.5$, $p < .05$). In addition, the replies that were received by the females were significantly less positive in nature than were those for other candidates.

Several studies, however, failed to demonstrate main effects for applicant sex. Fidell (1970) asked 147 psychology department chairpersons to evaluate the chances of 10 candidates' getting an offer for a full-time position. Sex of the candidates was varied. Although the mean ratings of male and female candidates did not differ, women were offered positions at significantly lower levels than the positions offered males.

Using an in-basket methodology, Terborg and Ilgen (1975) asked 36 male under-

Table 2
Summary of Studies Investigating Discriminatory Effects in Interviews

Study	Minority variables investigated	Other variables investigated	Major criterion used	Interviewer status and sample size	Type of job	Results	Comment
				Resume Studies			
Fidell (1970)	Sex		Desirability of candidates	147 chairpersons of psychology departments	Academic position	Males = females	No difference in mean ratings, but significant effect found in which men offered higher ranking positions
Shaw (1972)	Sex and handicap	Type of job	Hire rating	64 college recruiters	Management trainee or engineer	Males > females, $t = 1.81$, $p < .05$ Handicapped = non-handicapped, $t = 1.78$, *ns*	Greater bias against females for management trainee job
Wexley & Nemeroff (1974)	Race	Perceived similarity of applicants to interviewer	Hire recommendation	120 college students	Mechanical-engineer technician	Whites = blacks, $F = .34$, *ns*	Perceived similarity of biographical background was significant determinant of interviewer evaluation
Rosen & Jerdee (1974a)	Sex	Job demands	Overall hire rating	235 college students	Demanding job or clerical job	Males > females, $F = 14.02$, $p < .01$ Sex × Job demands, $F = 6.27$, $p < .05$	Females evaluated more severely when job requirements were demanding and challenging
Dipboye, Fromkin, & Wiback (1975)	Sex	Qualifications and attractiveness of candidates	Hire rating	30 college students and 30 professional interviewers	Head of furniture store	Males > females, $F = 15.84$, $p < .05$, $\eta < .01$ Qualified > unqualified, $F = 185.40$, $p < .01$, $\eta^2 = .34$	Qualified and attractive candidates more likely to be hired, regardless of sex

Table 2 (*continued*)

Study	Minority variables investigated	Other variables investigated	Major criterion used	Interviewer status and sample size	Type of job	Results	Comment
Cohen & Bunker (1975)	Sex	Type of job	Hire recommendation	150 job recruiters	Editorial assistant or personnel assistant	Job × Sex, $\chi^2(1) = 16.416, p < .01$	Females more acceptable for editorial jobs than personnel jobs; opposite true for males
Krefting & Brief (1977)	Handicap	Experience	Suitability for hire	145 college students	Typist position	Disability × Experience, $F = 4.58, p < .05$	Disabled, inexperienced applicant evaluated higher than experienced, disabled applicant
Rose & Brief (Note 1)	Handicap	Type of job	Satisfy customers	145 college students	Public contact job or supervisory job	Job × Health Status, $F = 11.18, p < .01$	Epileptics expected to satisfy clients more if hired for nonpublic job versus public job
Haefner (1977)	Race, sex, and age	Competence	Hire rating	286 managers	Semiskilled position	Males > females, $F = 78.53, p < .01$ Younger > older $F = 103.00, p < .01$ Competent > incompetent, $F = 544.92, p < .01$ Race × Sex, $F = 4.68, p < .05$ Race × Age, $F = 5.00, p < .05$ Sex × Competence $F = 10.54, p < .01$ Age × Competence, $F = 11.71, p < .01$	Among highly competent applicants, males and younger candidates preferred

Study	Minority variables investigated	Other variables investigated	Major criterion used	Interviewer status and sample size	Type of job	Results	Comment
Dipboye, Arvey, & Terpstra (1977)	Sex	Qualifications, attractiveness of applicants, sex, and attractiveness of interviewer	Hire rating	110 college students	Sales trainee	Males > females, $F = 20.44$, $p < .01$, $\eta^2 = .006$ Qualified > unqualified, $F = 563.93$, $p < .01$, $\eta^2 = .50$	Raters given choice of one candidate chose highly qualified male significantly more often than highly qualified female
Cash, Gillen, & Burns (1977)	Sex	Type of job and attractiveness of applicant	Hiring potential recommendation	72 personnel directors	Masculine, feminine, or neutral	Males > females for masculine jobs, $F = 7.28$, $p < .01$ Females > males for feminine jobs, $F = 21.83$, $p < .01$	
Muchinsky & Harris (1977)	Sex	Rater sex and qualifications	Recommendation to hire	100 college students	Mechanical engineer, day care, and copy editor	Females > males for rater sex, $F = 6.77$, $p < .05$ Females > males, $F = 11.36$, $p < .05$ Qualified > unqualified, $F = 256.39$, $p < .05$	Low- or medium-qualified females given higher evaluations than males on two of the three jobs
Heneman (1977)	Sex	Qualifications (through test scores)	Job suitability	144 college students	Life insurance agent	Qualified > unqualified, $\omega^2 = .22$ Qualifications × Sex, $\omega^2 = .02$	Highly qualified females rated less suitable than highly qualified males

Table 2 *(continued)*

Study	Minority variables investigated	Other variables investigated	Major criterion used	Interviewer status and sample size	Type of job	Results	Comment
Rose & Andiappan (1978)	Sex	Sex of raters and sex of potential subordinates	Probability of success	75 college students	Management position	Female raters > male raters, $F = 3.91$, $p < .0$, $\omega^2 = .33$; Applicant Sex × Predominant Sex of Subordinate, $F = 13.22$, $p < .01$, $\omega^2 = .42$	Female raters evaluated applicants of both sexes more positively than male raters; females expected to be more successful when subordinates were predominantly female
Renwick & Tosi (1978)	Sex	Job type, marital status, undergraduate major, and graduate degree	Ratings of general suitability	64 male and 16 female graduate students	Management with extensive travel and management with home office duties	Sex × Undergraduate Major × Graduate Degree × Marital Status, $F = 4.53$, $p < .006$	No effects found for sex
Zikmund, Hitt, & Pickens (1978)	Sex	Scholastic performance	Number of replies to letter	100 personnel directors	Accounting	$\chi^2(1) = 6.0$, $p < .01$	Greater response rate to letters using initials than to letters from female applicants
Kryger & Shikiar (1978)	Sex	Sex of author of letter of recommendation and favorableness of recommendations	Would proceed with interview	75 personnel managers	Managerial job	Females > males, $F = 5.3$, $p < .05$	Interpreted in terms of reverse discrimination

				In-basket studies			
Rosen & Jerdee (1974b)	Sex	Job complexity	Recommendation to hire	95 bank supervisors	Complex or routine	Males > females, $\chi^2(1) = 6.53$, $p < .05$	Interaction between job complexity and sex not significant
Terborg & Ilgen (1975)	Sex		Decision to hire and starting salary	36 college students	Engineer	Males > females on starting salary, $F = 4.51$, $p < .05$	No difference between male and female applicants in decision to hire but females given lower salary
Rosen & Jerdee (1976b)	Age		Suitability for job	142 college students	Job requiring high-risk judgments	Younger > older, $t = 2.91$, $p < .01$	Older employees evaluated as more resistant to managerial influences, less promotable to position requiring creativity, less likely to approve older workers' requests for transfer to job requiring high physical activity, and less likely to recommend support of training programs for older employees

Table 2 (*continued*)

Study	Minority variables investigated	Other variables investigated	Major criterion used	Interviewer status and sample size	Type of job	Results	Comment
				Videotape or field studies			
Rand & Wexley (1975)	Race	Rater racial prejudice and need for affiliation	Hiring recommendation	160 college students	Mechanical-engineer technician	Biographical similarity, $F = 24.22$, $p < .01$	Race not significant; similarity between applicant and interviewer significantly related to evaluations; more similar candidates given higher evaluations
Johnson & Heal (1976)	Handicap		Job offer	50 counselors at employment agencies		Nonhandicapped > handicapped, $r = .278$, $p < .01$	Handicapped applicant received significantly fewer job offers after visiting employment agency
Dipboye & Wiley (1977)	Sex	Aggressiveness of candidate	Recommended for hiring	66 college recruiters	Supervisor in retail department store	Males = females, aggressive > passive, $F = 37.41$, $p < .01$	No difference between males and females in recommendation for hiring, but females significantly evaluated more favorably on likability, qualifications, and suitability for job

graduates to evaluate male and female job candidates and found that while there was no difference in hire rating on the basis of applicant sex, females were assigned a significantly lower starting salary than were identical male applicants ($F = 4.51$, $p < .05$). This study is somewhat limited, however, by the small sample size and the use of college undergraduates as subjects. Dipboye and Wiley (1977) showed videotapes of aggressive and passive male and female applicants to 66 college recruiters and found that while aggressive candidates were evaluated significantly higher than passive candidates on an employability scale, there were no differences between the male and female interviewees. However, the recruiters perceived the females' overall qualifications and their experience and training as superior to those of the males. One possible problem associated with this study is that only one particular stimulus male and stimulus female were presented in the videotape conditions. Thus, the observed effects may have been unique to the specific individuals presented.

Renwick and Tosi (1978) asked 80 male and female graduate students to evaluate resumes for two managerial jobs; all applicants were portrayed as exceptionally well qualified. The applicant variables manipulated were sex, marital status, undergraduate major, and graduate degree. Each subject reviewed and evaluated 10 profiles. No evidence of differential evaluations as a function of applicant sex was found, except as a component of a four-way interaction.

A study by Muchinsky and Harris (1977) yielded results somewhat opposite to the previous findings. College students ($N = 100$) evaluated resumes that varied by applicant sex and qualifications for three different jobs (mechanical engineer, day-care person, and copy editor). Although numerous two- and three-way interactions were observed, a main effect ($F = 6.77$, $p < .95$) for applicant sex occurred in which females were given higher ratings than males.

A similar finding was observed in a related study by Kryger and Shikiar (1978). Personnel managers ($N = 75$) evaluated letters of recommendation of male and female candidates for a management-trainee job. Sex of the author of the letter of recommendation was manipulated, as was the favorableness of the letter. Subjects rated applicants in terms of whether the applicant should be interviewed. Results indicated that subjects were far more likely to proceed with an interview with female applicants than with male applicants ($F = 5.3$, $p < .05$). Kryger and Shikiar interpreted their results as being a function of affirmative action considerations by personnel managers. It should be noted that this study has more to do with whether an applicant is granted an interview than with decisions resulting from the interview itself. Although more females may be granted interviews, the decisions resulting from actual interviews may be unfavorable for women, as noted above.

In addition, several studies have revealed that both male and female raters give lower evaluations to female applicants. Studies by Dipboye et al. (1975) and Dipboye et al. (1977) showed that the observed effects are not confined only to male interviewers. However, when sex of the rater was investigated in the Rose and Andiappan (1978) and Muchinsky and Harris (1977) studies, significant main effects were observed in which female raters gave significantly higher ratings to applicants of both sexes than did male raters. Thus, there is some indication that female raters are more lenient than male raters, which corresponds to the findings of London and Poplawski (1976), in which females were observed to give more lenient evaluations of stimulus objects in a study involving the formation of stereotypes. However, Renwick and Tosi (1978) found no evidence of a sex-of-interviewer effect.

In addition to simply searching for main effects, research has focused on several variables that are predicted to interact with applicant sex in influencing the evaluations given. The variable given the most attention is the type of job for which the candidates are considered. Typically, a prediction is made that females will be given lower evaluations compared with males when being considered for jobs assumed to be masculine in nature, that is, jobs that are either pre-

dominantly held by males (Muchinsky & Harris, 1977) or jobs that reflect demanding or challenging activities (Rosen & Jerdee, 1974b). What is proposed is a sex-congruency model whereby a situation or job is sex typed as being more appropriate for a male or a female and thereby influences the evaluation given.

To date the research provides fairly consistent evidence confirming the sex-congruency notion. Studies by Shaw (1972), Cohen and Bunker (1975), Cash, Gillen, and Burns (1977), and Rosen and Jerdee (1974b) show significant interactions between sex and type of job in their influence on evaluations. However, the study by Muchinsky and Harris (1977), in which individuals evaluated male and female resumes for jobs in mechanical engineering (traditionally masculine), a child-care center (traditionally feminine), and journalism (a neuter job), indicated only mixed support for the hypothesis of differential evaluations as a function of job type and sex. In different contexts, Feather (1975) and Feather and Simon (1975) found evidence for the differential evaluation of males and females as a function of the appropriateness of the occupation for one or the other sex.

An additional job variable that has been investigated is the predominant sex of the subordinates in the job. Rose and Andiappan (1978) hypothesized that greater differential evaluations of male and female job candidates would occur when interviewers evaluated such candidates for managerial jobs that involved either a predominantly male or a predominantly female work force. Male ($n = 55$) and female ($n = 20$) college students evaluated resumes for a managerial position. Sex of subject, sex of applicant, and predominant sex of subordinates were the variables investigated. The results of their resume study indicated that female candidates were evaluated more favorably when the predominant sex of the subordinate employees was female. Likewise, male candidates were given higher evaluations when their potential subordinate work force was predominantly male.

A further variable that has been investigated in several studies is applicant qualifications or competence. Two basic questions were behind the investigations of the effects of applicant qualifications. First, researchers were interested in whether significant sex effects emerged simply because sex was the only salient cue in the stimulus set and whether when sex was considered jointly with qualifications the sex effects would diminish or even disappear because of the powerful effect of the qualification variable. A second question concerned the possible interaction between applicant sex and qualifications and whether interviewers evaluate highly competent females more poorly than highly competent males in comparison with the differences in evaluations that occur when the candidates are not so well qualified (Spence & Helmreich, 1972). These predictions were based on the notion that highly competent or qualified women are particularly threatening to male interviewers. Several studies bear directly on these issues. Dipboye et al. (1975) found a large main effect for competence: Highly qualified job candidates were preferred over less qualified candidates. Although the sex of the applicant was still a significant main effect, it accounted for less than 1% of the variance in the ratings compared with 38% accounted for by the qualification variable. On the other hand, when subjects were asked to choose only one candidate from the resumes, 72% of them chose a male. Finally, there was no indication of an interaction between applicant qualifications and applicant sex.

Similar results were obtained by Dipboye et al. (1977). Although applicant qualifications accounted for a large portion of the evaluation variance compared with that accounted for by applicant sex (50% vs. .006%), when subjects were asked to choose only one candidate for hire, highly qualified males were selected by 54% of the subjects, whereas 28% chose the highly qualified females. This difference was significant at the .05 level.

The study reported by Muchinsky and Harris (1977) indicated that significant differences were found between males and females of average ability (as indicated by

scholastic standing) but that no differences occurred between male and female applicants at high or low ability levels.

Heneman (1977) reported a study in which 144 college students evaluated hypothetical applicants for the job of life insurance agent. The qualifications of applicants were manipulated indirectly through the use of test scores. In this study, highly qualified females were evaluated as being much less suitable for hire than were highly qualified males.

Finally, the resume study conducted by Haefner (1977) found that while highly competent individuals were preferred over less competent candidates, preferences were clearly given to highly competent males over highly competent females. Two research trends are suggested by these data. First, although qualifications of candidates are clearly the most powerful factors in influencing interviewers' decisions, sex of applicant remains a significant variable. Moreover, although the sex of the applicant does not appear to account for a great deal of rating variability, when only one or two hiring choices are given to evaluators, sex of the applicant is a highly important variable. This situation is analogous to the utility of a test that has low validity but is used in a situation in which a large number of candidates are considered and only a small number of jobs are available. The low selection ratio gives a test with low validity a high degree of utility (Wiggins, 1973).

The findings regarding the predicted interaction of applicant qualifications with rater sex are mixed. Some studies demonstrate support for this notion and others do not, or they indicate interactions other than those predicted.

An additional variable that was investigated in three studies is the attractiveness of the job candidates. Dipboye et al. (1975) investigated the notion that physical attractiveness may be a more important variable in influencing interview evaluations for females than for males. However, their results showed that attractive candidates were preferred over unattractive candidates regardless of sex. A second study by Dipboye et al. (1977) showed different results. Attractive males were rated significantly higher than were attractive females, and unattractive males were rated higher than were unattractive females, but no difference occurred between male and female candidates who were moderately attractive.

The third study investigating this variable was more complex. Cash et al. (1977) made several predictions:

1. When candidates are under consideration for neuter jobs (i.e., jobs that are not considered traditionally male or female, attractive applicants will be more favorably evaluated than unattractive candidates, regardless of sex.

2. When candidates are considered for a traditionally masculine job, attractive males will be more highly evaluated than attractive females. In contrast, when under consideration for a traditionally feminine job, attractive females will be more positively evaluated than attractive males.

Results of the study indicated that these predictions were for the most part confirmed. In summary, attractiveness is an important factor for both males and females, but may influence interviewers' decisions differently for males and females, again depending on the type of job under consideration.

Applicant Race

Somewhat surprisingly, only three studies have dealt with race of the applicant in interview evaluations. Even more surprising, however, is that little evidence was found to suggest that interviewers give more unfavorable evaluations to black job candidates compared with white candidates.

Wexley and Nemeroff (1974) conducted a study in which resumes of blacks or whites were presented to 120 students who were asked to evaluate either black or white candidates with regard to their suitability for the position of mechanical-engineer technician. In addition, each resume contained information indicating whether the candidate was relatively similar in background to the interviewer (e.g., father was an office worker and mother a school teacher) or dissimilar in background to the interviewer (e.g., father was a laborer and mother a domestic work-

er). The students were also divided into relatively high and low racially prejudiced groups on the basis of their scores on an attitude measure of prejudice. The results indicated that the race of the applicant had no effect on the employability ratings given. However, similarity of biographical background did prove to be a major determinant of the evaluations of job candidates. Moreover, interviewers who were relatively more prejudiced tended to give lower ratings to both white and black applicants than did interviewers who were relatively less prejudiced.

Haefner (1977) also used a resume design and found that race interacted with both sex and age to influence interviewers' evaluations, but these effects were very small.

Finally, Rand and Wexley (1975) showed 80 white males and 80 white females videotapes of employment interviews in which a black or white applicant was presented. Again, race of the applicant did not significantly affect the evaluations of the candidates. Additional results showed that biographical similarity and racial prejudice on the part of interviewers influenced the evaluations given, but these factors operated to influence the ratings of both black and white applicants. Thus, not a great deal of research evidence is available that demonstrates that interviewers give lower evaluations to black applicants who have qualifications equal to those of white applicants.

A factor that might account for the paucity of significant findings is that the studies were conducted within the past 5 years and that the interviewers generally consisted of students who may have been somewhat liberal or sensitive to the EEOC and legal issues associated with evaluating black applicants for jobs. They might have been apt to respond somewhat differently if they had not been sensitized to these issues. A further factor is that all the studies except that reported by Haefner (1977) used between-subjects designs in which subjects viewed only one stimulus condition (either the black or white applicant). Within-subject designs have two advantages that might be capitalized on in future studies: First, given the same total number of subjects, there are more degrees of freedom, thus making an experiment relatively more powerful in detecting differential evaluations if they, in fact, occur; second, subjects are allowed to view more than one stimulus condition, which allows them to establish anchor and reference points on the rating scales. The between-subjects designs in the studies reported above may have simply not been powerful enough to detect significant effects.

Applicant Age

Only two studies have investigated the effects of candidates' age on interviewers' evaluations. Haefner (1977) found that age was a significant factor in interviewers' evaluations and that age also interacted with race (as noted above) and with competence. Although age played no role in the evaluation of barely competent candidates, younger highly competent individuals were preferred over relatively older but highly competent individuals.

Using the in-basket methodology, Rosen and Jerdee (1976b) found some interesting results. Undergraduates ($N = 142$) reacted to six items embedded in an in-basket in which age was the variable manipulated. Older employees were evaluated as less suitable for a job compared with younger employees. In addition, the older employees were evaluated as (a) less promotable, (b) more resistant to change, (c) having lower physical capability, and (d) less likely to have organizational support for retraining opportunities. Although these two studies suggest a rather strong and pervasive effect due to applicant age, more research is needed to substantiate these findings.

Applicant Handicap

There is a relative dearth of studies demonstrating the effects (or lack of effects) of handicapped status on interview evaluations. An early study by Shaw (1972), for example, investigated the differential evaluation of job candidates when one was depicted as an individual with a "withered arm" and weak vision. Subjects were 132 college recruiters. Although no significant effects were

observed, the results indicated that the candidate with the physical disability was perceived relatively favorably. The authors' explanation was that subjects perceived the candidate "as a courageous figure who had overcome physical adversity, rather than an employment risk because of physical handicaps" (Shaw, 1972, p. 337).

Krefting and Brief (1977) reported the results of a study in which 145 college students evaluated a packet of resumes and other materials necessary for determining whether an applicant should be hired for the position of typist. The applicant in the resume was depicted as either healthy or confined to a wheelchair. Also, the applicant was depicted as either experienced or nonexperienced.

The individuals reviewing the resume materials gave estimates of the applicant's health, motivation, potential for staying, and so forth in addition to an overall rating. Disabled applicants were seen as significantly more highly motivated and as more likely to become long-term employees than were nondisabled applicants. However, a puzzling interaction also occurred. The inexperienced, disabled applicant was evaluated higher overall than was the experienced, disabled applicant. The authors suggested that the results of the study were relatively encouraging for qualified, disabled applicants. One of the problems with this and similar studies is that the subjects may have guessed the purpose of the study because of the nature of the applicant variable (i.e., handicapped status) displayed.

In a second study along these lines, Rose and Brief (Note 1) assessed the impact of applicant disability (epilepsy) and job type on evaluation judgments. Students ($N = 145$) evaluated a resume and other data that portrayed the applicant as either healthy or having epilepsy (although the seizures were under control). Applicants were portrayed as applying for a job that involved either a great deal of public contact and supervisory responsibilities or no public contact or supervisory responsibilities. Subjects gave evaluations along several dimensions. Results indicated that epileptic and normal applicants were not perceived to be significantly different in terms of their overall performance, tenure with the firm, work effectiveness, and amount of salary. There was, however, a significant interaction between disability and type of job on several evaluations. Epileptics seeking non-public-contact jobs were perceived as more likely to satisfy clients than were normal applicants.

A third study is perhaps not so encouraging. Johnson and Heal (1976) reported the results of a study that again compared a wheelchair job applicant with a healthy applicant. In this study, actual employment agencies (50) were visited by one of the researchers, who indicated interest in finding a job. However, in half the interviews, the same researcher appeared in a wheelchair. The researcher rated the agency responses on a number of variables. The analyses of the data showed that handicapped applicants as opposed to healthy applicants were offered significantly fewer future job interviews and given a more gloomy estimation of the job market by the agency representatives. In addition, the representatives gave the handicapped applicants a lower probability of getting the kind of work that was being sought and offered relative discouragement to the handicapped applicants about seeking a position with normal public exposure.

The results of this study may have been influenced by the fact that the researcher did the ratings herself. However, the findings certainly suggest that interviewers may give less favorable evaluations to individuals displaying a handicap.

Summary of Evidence Concerning Differential Evaluations

A review of the research concerning differential evaluations of minority job candidates based on components of the interview yields mixed results. First, the evidence based on the resume research is fairly consistent in showing that women tend to be evaluated more poorly than men. Moreover, the degree of differential evaluation appears to be related to the type of job for which women are considered; a more prominent bias occurs when women are considered for typically masculine-oriented jobs.

When qualifications of candidates are considered, research studies tend to demonstrate the following: (a) Qualifications of job candidates show a powerful main effect that accounts for 25%–50% of the variance in ratings; (b) the predicted interaction between applicant qualifications and sex was not consistently found and, in particular, did not support the notion that highly competent women are prone to more negative evaluations compared with highly competent males in relation to differences between less qualified male and female applicants.

A somewhat surprising finding is the paucity of evidence for differential evaluation of job candidates as a function of race. Although only a few studies have investigated this phenomenon, the data do not support typical a priori assumptions about the interview's providing a ready mechanism by which to discriminate against blacks.

This review also reveals a relative dearth of research investigating the possible bias in interview circumstances that operates to negatively affect elderly applicants as well as those with handicaps. Although the existing studies suggest a strong and pervasive effect due to applicant age, the data dealing with handicapped applicants are more complex. The few studies that have explored this issue suggest that handicapped applicants are viewed as having higher motivational tendencies, possibly because of the perceptions of interviewers that handicapped applicants must have exerted a great deal of effort, worked harder, and so on in order to overcome their disabilities. Obviously, more research needs to be performed on the kinds of evaluations handicapped individuals receive in employment settings.

Differential Validity of the Interview

A major thrust of the 1970 EEOC guidelines on testing was the need for employers to investigate the possibility that a selection device may exhibit differential validity. Boehm (1972) and Humphreys (1973) have indicated that differential validity has to do with whether the correlation between predictor and criterion for one subgroup of a population differs significantly from the correlation between a predictor and criterion for a different subgroup of a population.

Although numerous studies have examined the validity of the interview and interview process in general (Mayfield, 1964; Ulrich & Trumbo, 1965; Wright, 1969), only three studies were located that examined the validity of the interview as a function of employee subgroup characteristics.

Lopez (1966) reported the results of a study in which black and white female applicants for toll collection jobs were given a standardized 10-minute biographical data interview in which training, experience, and personal qualifications were numerically assessed. Although the study was seriously flawed, the data indicated that the interview was significantly correlated with toll accuracy and length of time in service for whites. For the black sample, the interview was significant when correlated against the criteria of attendance, toll accuracy, length of service, and supervisor's appraisal. However, these results are extremely suspect because the correlations were corrected for restriction of range, sample size values were not reported for the separate groups, and tests of differential validity were not conducted.

Kirkpatrick, Ewen, Barrett, and Katzell (1968) reported validity coefficients separately by race. Interviewers' ratings based on a 5-point scale were correlated against six different criterion measures for 94 white and 22 black female clerical workers. The interview ratings lacked validity in the total sample and in each group separately. Thus, the differential validity hypothesis was not supported;[15] judgments based on the interview were invalid for both groups. In addition, no difference was observed between the ratings given to the black and white groups by interviewers.

Freytag (Note 2) reported the results of a study designed to investigate the differential validity of the interview in predicting performance of 64 minority members (blacks, females, Hispanics, etc.) and 54 white pa-

[15] These authors tested for differential validity incorrectly, but since both coefficients did not differ significantly from zero, one can infer that no differential validity occurred in this instance.

trol officers. Interview ratings based on a three-man oral board were correlated with performance ratings. Only interview ratings of the officers' communication skills correlated significantly for the total sample; however, a test of differential validity indicated that the interview was equally valid for both groups.

To summarize these three studies, very little evidence exists that indicates that the interview is differentially valid for minority group members and nonminority members. On the other hand, little evidence indicates that the phenomenon does not exist because of the paucity of research investigating this issue.

Concluding Comments and Needed Research

For a selection device that is so widely used, we know very little about its discriminatory impact on minorities. Given the high probability that the interview will be subject to greater judicial review, it is somewhat startling to realize that only a little over 20 studies have investigated the issue of differential evaluations or validity of the interview.

Throughout this article, a number of research needs have been identified. Some of these are described below.

Methodological Needs

More research is needed that uses different methodologies in investigating possible differential evaluation or bias in the interview. Presently, there seems to be an overreliance on resume techniques. It seems likely that evaluations given to "pencil-and-paper" people differ from those given to more fully described and portrayed stimulus people. More efforts should be made to study in vivo interview simulations or to use methodologies that present fuller stimulus fields of the interview situation. The studies by Wexley and Nemeroff (1974), Wexley, Sanders, and Yukl (1973), and Dipboye and Wiley (1977) are excellent examples of the presentation of stimulus material through videotape techniques. In addition, more efforts to conduct field research using the methodology suggested by Johnson and Heal (1976) should be made. Face-to-face interviews also need to be studied.

Future researchers may also want to explore some Bayesian methodologies, concepts, and approaches (Hayes, 1973; Slovic & Lichtenstein, 1971) in consideration of the differential evaluation issue. Such techniques might be used to examine the revision of interview judgments or prior probabilities of interviewers' success as more information about candidates becomes available. Prior probabilities of success in jobs for minorities may be more resistant to change than prior probabilities for nonminorities. Moreover, the prior-probability distributions may themselves be different based on the minority/majority status of the interviewee. Osburn and Constantin (Note 3) suggested that interviewers, when lacking information on bona fide qualifications, respond as if women have a lower probability of success in jobs traditionally held by women. Thus, the formation of differential evaluations of candidates might be viewed from a Bayesian perspective.

Between-subjects and within-subject designs need to be contrasted with regard to the information they yield regarding differential evaluations. Within-subject designs may be more powerful in detecting differential evaluation for two reasons: First, from a statistical perspective, more degrees of freedom are available. Second, interviewers themselves may be more prone to give differential evaluations when they have comparative stimulus sets of interviewees.

Researchers also need to tap subject pools other than undergraduate and graduate students. Though some research indicates that college student reactions are not appreciably different from those of managers (Bernstein, Hakel, & Harlan, 1975; Dipboye et al., 1975), more real-life interviewers need to be used in research of this sort.

Finally, researchers should be more aware of the need to present greater stimulus sampling in the conditions presented; that is, subjects should have the opportunity to view more than one particular female or handicapped individual in studies of this kind. Otherwise, any significant effect observed

might be unique to the specific stimulus individual presented because of other uncontrolled minor characteristics (hair color, height, etc.). Pools of stimulus applicants from which samples can be drawn to show subjects should be developed.

Research on Race, Age, and the Handicapped

Research is needed to further establish whether interview judgments are biased against the elderly, the handicapped, or other minorities. Little interview research has been conducted on these minorities. Given the relatively high probability of more lawsuits' occurring in these areas, it would be wise to focus greater research efforts on studying the interview as it may impact on these particular groups. For example, an area of research that demands further exploration is the notion that subjects overevaluate handicapped applicants (Krefting & Brief, 1977). Perhaps in these situations subjects attribute higher motivation, ability levels, and so forth to handicapped individuals filing applications for jobs because of their perceived efforts to overcome their disabilities.

Further research might also focus on differential evaluations as a function of type of disability. Some disabilities (e.g., mental illness) are perceived more negatively by employers than are other disabilities (Nagi, McBroom, & Colletts, 1972). Thus, lower evaluations may be given to applicants with the most negatively viewed disability or handicap.

Similarly, research is needed to investigate a possible Age × Type of Job interaction. It seems likely that there are some jobs in which older individuals are perceived as the more desirable candidates (e.g., president of company, chairperson of board) and some jobs in which old age is perceived as a handicap (e.g., airplane pilot). The possible interactions need to be explored.

Process Research

More research is needed to determine what goes on in interviews to influence differential evaluations; that is, researchers should begin to focus on the underlying process by which differential evaluations take place. As noted earlier, the exact methods by which stereotypes affect interviewer judgments are not known. Do interviewers base their differential judgments on the matching or the stereotyping paradigms described earlier?

Many of the questions asked earlier about the process of interviewer judgments (Webster, 1964) need to be further examined in the context of differential evaluations. For example, a number of process issues and areas need further investigation. When do differential evaluations occur during the interview process—early or late? Do interviewers gather different kinds of information or pay attention to different information depending on the majority or minority status of the candidate? Policy-capturing methodologies along the lines of those employed by Zedeck and Kafry (1977) might be useful in these contexts.

What kinds of differences occur between studies that examine the impact of face-to-face contact with applicants and studies that assess candidates on the basis of resumes? Imada and Hakel (1977) showed that nonverbal communication (e.g., eye contact, posture, gesturing, etc.) has a strong impact on interviewer decisions. These behavioral components of the interview process need to be examined with regard to their impact on differential evaluations. In short, more molecular studies of the verbal and nonverbal aspects of the interview need to be carried out.

Does the amount of information about candidates and jobs affect differential evaluations? Studies by Longsdale and Weitz (1973) indicate that interviewers are more prone to agree about job candidates when there is a great deal of information concerning the job than when there is not much information about the job. Wiener and Schneiderman (1974) conducted two experiments showing that complete and unambiguous job information reduces the effect of irrelevant stereotypes on interviewer decisions. Does this also result in a minimization of differential evaluations? Similarly, does providing more information about the applicant also serve to decrease differential evaluations?

Strength of Effects

Analyses that yield precise estimates of the proportion of variance accounted for by the minority/majority status of the candidates in interview situations need to be carried out. The few studies that have calculated and presented such estimates indicate that minority status accounts for relatively small amounts of the variation. Yet, such effects may have decidedly powerful effects when only a small number (e.g., one) of the candidates are chosen as the best or most likely candidates.

Differential Validity and Regression

More research is needed to investigate the possibilities of differential regression in the interview. Is the interview equally valid for blacks and whites, women as well as men, and so on? It may be that if interviewers collect and process different information in an interview based on the minority/majority status of job candidates, then the interview may indeed show different patterns of validity with different job criterion measures. Similarly, more psychometrically sophisticated models should be used in reviewing the fairness of the interview.

Interviewer Training

Does interviewer training affect the kinds of evaluations given to minority and majority job candidates? Studies by Wexley et al. (1973) and Latham, Wexley, and Purcell (1975) have shown that workshop training of interviewers geared toward the reduction of rating errors is fairly effective. Do efforts to provide interviewers with training about how to interview minorities, what questions to avoid, and so forth result in more accurate evaluations and the reduction of differential evaluation? To date no studies exist concerning these issues.

Interviewer Variables

Additional efforts should be made to explore possible factors associated with the interviewer that may affect any differential evaluations given. Arvey, Passino, and Lounsbury (1977) found that sex of the evaluator showed marginal effects on the gathering of job analysis data. London and Poplawski (1976) reported that females tend to make more favorable evaluations than do males. In addition, Rumenik, Capasso, and Hendrick (1977) summarized a number of studies concerning sex of the interviewer and concluded that this variable is indeed a potent one.

Moreover, other interviewer characteristics should be investigated with regard to their possible influence on differential evaluations. For example, Rose and Andiappan (1978) suggested that the interviewer differences in androgyny may influence differential evaluation.

Integration of Findings With Other Research

Research should be conducted that resolves the conflict between many of the findings gathered in the context of interview research and those gathered in other contexts. For example, Hamner, Kim, Baird, and Bigoness (1974), Bigoness (1976), and Jacobson and Effertz (1974), among others, have found that females are evaluated more favorably when raters evaluate performance. Why the results from these studies differ substantially from those summarized earlier needs to be determined.

It is hoped that the present article will serve to direct and foster future research efforts. The last word about the interview is a long way from being said.

Linear Models for the Analysis and Construction of Instruments in a Facet Design

Gideon J. Mellenbergh, Henk Kelderman, Jenneke G. Stijlen, and Edu Zondag
University of Amsterdam, Amsterdam, The Netherlands

Linear models are described for the situation wherein a measurement instrument is constructed for all elements of the Cartesian product of several facets when the elements of each facet are not ordered. The structure of the covariance matrix of the instrument is derived from the models. By using covariance structure analysis, the models can be tested, and estimates of the parameters can be obtained. Models for 20 tests were formulated and tested and were constructed from a design with a behavioral and a situational facet measuring social anxiety in children; for 15 tests a model proved to fit the data. It is concluded that covariance structure analysis is useful for the analysis and construction of measurement instruments.

Facet designs can be used for test item writing. A facet is a set consisting of a finite number of elements (Foa, 1965). The Cartesian product of a finite number of facets is a design for item and test construction. This design for test construction corresponds to the factorial design for experimentation. Facet designs have been used in different areas of psychological and educational measurement. For example, Guttman and Schlesinger (1967) constructed distractors for ability and achievement items from facet designs. Hamersma, Paige, and Jordan (1973) reported facet designs for the construction of attitude scales. Butt and Fiske (1968) compared dominance scales constructed from a facet design with dominance scales developed using other strategies. Guilford's (1967) structure-of-intellect model can be conceived as a facet design (Fiske, 1971, p. 128). The multitrait–multimethod matrix (Campbell & Fiske, 1959) results from a facet design: The correlation coefficients of this matrix are computed between the elements of the Cartesian product of a facet with traits and a facet with methods.

Scores from tests constructed in a facet design can be analyzed using generalizability theory (Cronbach, Gleser, Nanda, & Rajaratnam, 1972). For example, Endler and Hunt (1966) used a facet design with 11 situations and 14 modes of response. For each combination of situation and mode of response a 5-point scale was constructed. By considering subjects as elements of a separate facet and by assuming that the elements of each facet are a random sample from a universe, variance components were estimated for the situations, the modes of response, the subjects, and their interactions. Scores from tests constructed in a facet design can also be analyzed using three-mode factor analysis (Tucker, 1963). For example, Levin (1965) analyzed the Endler and Hunt data with this technique. The results of this analysis are three matrices: one with factor loadings of the situations, one with factor loadings with the responses, and a core. The core contains the scores for the interaction of situations and responses for types of subject.

Another approach is the analysis of measures of association between the instruments constructed in a facet design. For example, Schlesinger and Guttman (1969) computed correlation coefficients between intelligence

We thank David A. Kenny, Fred N. Kerlinger, Wim J. van der Linden, Wim E. Saris, and Pieter Vijn for their comments and Ineke Wesling for typing the manuscript.

and achievement tests in a facet design; they used smallest space analysis for the analysis of the correlation matrix. Bock and Bargmann (1966) analyzed covariance matrices of tests constructed in a facet design. They considered the elements of the facets from which the tests were constructed as fixed and the elements of the facet with subjects as random. Assuming that the observed scores were linear functions of a set of uncorrelated latent variables, they analyzed the covariance matrices and estimated the variances of the latent variables. Wiley, Schmidt, and Bramble (1973) generalized the models considered by Bock and Bargmann.

New models have recently been developed for the analysis of covariance matrices: Hypotheses about the structure of the matrix can be formulated and tested; estimates of the parameters in the hypothesized model can be computed (Bentler, 1976; Jöreskog, 1970, 1973; Long, 1976; Mukherjee, 1973). A facet design is preeminently suited to generating and formulating hypotheses about covariance matrices. Covariance structure analysis should therefore be considered as an important method for the analysis of covariance and correlation matrices computed between instruments constructed from a facet design; it can further an "integration of test design and analysis" (Guttman, 1970).

Linear models are formulated for facet designs. The models are applied to a correlation matrix of 20 instruments from a facet design measuring social anxiety in children. Using covariance structure analysis several models were tested; parameter estimates are reported for the model that best fits the data.

Models for Facet Designs

The situation wherein the elements of a facet are not ordered is considered; instruments are constructed for all elements of the Cartesian product of the facets. A general model for this situation is described; from this model special cases are derived. For the sake of simplicity, the models are described for two facets with p and q elements; the models can easily be generalized to more than two facets. The two facets can be represented by a rectangle with p rows and q columns. Each square of the rectangle represents an element of the Cartesian product of the two facets (for an example, see Table 1). It is assumed that for each element of the Cartesian product, one measurement instrument is constructed.

It is also assumed that the score of Subject i on the instrument from the jth row and the kth column is a linear function of a set of latent variables:

$$y_{ijk} = m_{jk} + s_{jk}S_i + r_{jk}R_{ij} + c_{jk}C_{ik} + rc_{jk}RC_{ijk} + E_{ijk}. \quad (1)$$

In this equation m_{jk} is the mean score on the instrument in the population of subjects; the parameters s_{jk}, r_{jk}, c_{jk}, and rc_{jk} are loadings specific to the jth row and the kth column of the facet design. The other terms in the equation represent the scores of Subject i on random latent variables: S_i is the score on a general latent variable, R_{ij} and C_{ik} are the scores on

Table 1
Cartesian Product of a Situational and Behavioral Facet for Social Anxiety in Children

Situational facet	Behavioral facet: Cognitive	Avoidance	Physiological	Affective
Social	Social–cognitive (y_{11})	Social–avoidance (y_{12})	Social–physiological (y_{13})	Social–affective (y_{14})
Intellectual	Intellectual–cognitive (y_{21})	Intellectual–avoidance (y_{22})	Intellectual–physiological (y_{23})	Intellectual–affective (y_{24})
Physical	Physical–cognitive (y_{31})	Physical–avoidance (y_{32})	Physical–physiological (y_{33})	Physical–affective (y_{34})
Exclusion	Exclusion–cognitive (y_{41})	Exclusion–avoidance (y_{42})	Exclusion–physiological (y_{43})	Exclusion–affective (y_{44})
Appearance	Appearance–cognitive (y_{51})	Appearance–avoidance (y_{52})	Appearance–physiological (y_{53})	Appearance–affective (y_{54})

latent variables specific to the jth row and the kth column, and RC_{ijk} is the score on a latent variable specific to the combination on the jth row and the kth column; E_{ijk} is the error score. The terms RC_{ijk} and E_{ijk} are both scores of Subject i on latent variables specific to the combination of the jth row and the kth column and cannot be separated without replications. Therefore, the term $rc_{jk}RC_{ijk}$ is absorbed into the residual term: $E_{ijk}^* = rc_{jk}RC_{ijk} + E_{ijk}$; omitting the asterisk in the residual yields the following model:

$$y_{ijk}=m_{jk}+s_{jk}S_i+r_{jk}R_{ij}+c_{jk}C_{ik}+E_{ijk}. \quad (2)$$

Restricting parameters in Equation 2 yields special cases. First, one or two of the parameters s_{jk}, r_{jk}, and c_{jk} are set equal to zero:

$$y_{ijk} = m_{jk} + r_{jk}R_{ij} + c_{jk}C_{ik} + E_{ijk}; \quad (3)$$

$$y_{ijk} = m_{jk} + s_{jk}S_i + c_{jk}C_{ik} + E_{ijk}; \quad (4)$$

$$y_{ijk} = m_{jk} + s_{jk}S_i + r_{jk}R_{ij} + E_{ijk}; \quad (5)$$

$$y_{ijk} = m_{jk} + s_{jk}S_i + E_{ijk}; \quad (6)$$

$$y_{ijk} = m_{jk} + r_{jk}R_{ij} + E_{ijk}; \quad (7)$$

$$y_{ijk} = m_{jk} + c_{jk}C_{ik} + E_{ijk}. \quad (8)$$

Second, the parameters can be set equal to one; Equation 2 reduces to

$$y_{ijk} = m_{jk} + S_i + R_{ij} + C_{ik} + E_{ijk}. \quad (9)$$

This model can be restricted, thus further eliminating one or two of the latent variables. Third, in Equations 2–9 parameters can be constrained in the sense that they are set equal to each other.

Equation 2 can also be formulated in vector notation:

$$y_{ijk} = m_{jk} + \mathbf{l}'_{jk}\mathbf{f}_i + E_{ijk}, \quad (10)$$

where $\mathbf{f}'_i$ is the vector with the scores of Subject i on all latent variables $[\mathbf{f}'_i = (S_i, R_{i1}, \ldots, R_{ij}, \ldots, R_{ip}, C_{i1}, \ldots, C_{ik}, \ldots, C_{iq})]$ and $\mathbf{l}'_{jk}$ is the vector with three parameters in positions corresponding to the positions of the elements S_i, R_{ij}, and C_{ik} in the vector $\mathbf{f}'_i$ and is zero otherwise $[\mathbf{l}'_{jk} = (s_{jk}, 0, \ldots, r_{jk}, 0, \ldots, c_{jk}, 0, \ldots)]$. The models displayed in Equations 3–8 can also be written in the form of Equation 10 by setting the appropriate elements of the vector $\mathbf{l}'_{jk}$ equal to zero; the model in Equation 9 is written in the form of Equation 10 by setting the three parameters of the vector $\mathbf{l}'_{jk}$ equal to one.

In Equation 10 the score of Subject i on one instrument is considered. However, for Subject i scores are obtained on all $p \times q$ instruments. The scores of Subject i on the instruments are collected in one observation vector: $\mathbf{y}'_i = (y_{i11}, \ldots, y_{i1q}, y_{i21}, \ldots, y_{i2q}, \ldots, y_{ip1}, \ldots, y_{ipq})$. From Equation 10 follows the model for the vector of observations of Subject i:

$$\mathbf{y}_i = \mathbf{m} + \mathbf{L}\mathbf{f}_i + \mathbf{e}_i, \quad (11)$$

where the vector $\mathbf{m}' = (m_{11}, \ldots, m_{1q}, m_{21}, \ldots, m_{2q}, \ldots, m_{p1}, \ldots, m_{pq})$ contains the population means of all instruments; the vector $\mathbf{e}'_i = (E_{i11}, \ldots, E_{i1q}, E_{i21}, \ldots, E_{i2q}, \ldots, E_{ip1}, \ldots, E_{ipq})$, the residuals of Subject i on all instruments; and $\mathbf{L}$ is the matrix with rows $\mathbf{l}'_{jk}$: $\mathbf{L}' = (\mathbf{l}_{11}, \ldots, \mathbf{l}_{1q}, \mathbf{l}_{21}, \ldots, \mathbf{l}_{2q}, \ldots, \mathbf{l}_{p1}, \ldots, \mathbf{l}_{pq})$. It is assumed without loss of generality that the latent variables have zero population means, with covariance matrix $\mathbf{E}^2$ for the residuals and $\mathbf{C}$ for the other latent variables. From the assumption that the population covariances between the residuals and the other latent variables are zero and from Equation 11, it follows that the population covariance matrix $\mathbf{S}$ of the observed scores on the instruments has the following structure (Jöreskog, 1974):

$$\mathbf{S} = \mathbf{LCL}' + \mathbf{E}^2. \quad (12)$$

The restrictions on the parameters mentioned above give rise to special cases of the matrix $\mathbf{L}$. Equation 6 implies that only the first column of $\mathbf{L}$ contains parameters; the other elements are zero. The model is a one-factor model; if this model fits the data, the instruments are termed *congeneric* tests (Jöreskog, 1971, 1974). The models displayed in Equations 3, 4, 5, 7, and 8 imply that the matrix $\mathbf{L}$ contains columns with both parameters and zeros; the models are restricted factor models (Lawley & Maxwell, 1971, chap. 7). Equation 9 implies that $\mathbf{L}$ is a matrix with zeros and ones, which in experimental design models is termed a *design* or *incidence* matrix (Searle, 1971, p. 166); the model is a variance component model (Jöreskog, 1974).

Assumptions about the covariances between the latent variables yield special cases of the matrices $\mathbf{C}$ and $\mathbf{E}^2$ in Equation 12. Assuming

that the population covariance of the residuals of the instruments is zero implies that $\mathbf{E}^2$ is a diagonal matrix with the variances of the residuals on the diagonal. From the assumption that the population covariances of all latent variables are zero, it follows that $\mathbf{C}$ is a diagonal matrix with the variances of the latent variables on the diagonal; assuming that the population covariances of only some of the latent variables are zero implies that the matrix $\mathbf{C}$ contains covariance parameters and zeros. In practical applications the investigator should state his or her assumptions regarding the population covariances of the latent variables.

These points can be illustrated by the multitrait–multimethod matrix. The model for this matrix is Equation 3: r_{jk} are the loadings on the trait factors and c_{jk} on the method factors. The matrix $\mathbf{L}$ contains a column for each trait factor and a column for each method factor. Each instrument has exactly one parameter for the corresponding trait factor and one parameter for the corresponding method factor (Jöreskog, 1971). In the most general formulation it is assumed that all factors are correlated (Werts & Linn, 1970) and that all elements of the matrix $\mathbf{C}$ are parameters. A special case is obtained by assuming that the trait factors are correlated and that the method factors are correlated but that the trait factors are not correlated with the method factors (Alwin, 1974). The matrix $\mathbf{C}$ contains parameters and zeros. A further restriction can be made by assuming that the effects of a given method are constant (Alwin, 1974). This implies that some parameters in the matrix $\mathbf{L}$ are constrained: The parameters in a column for a method factor are set equal to each other.

Equations 2, 4, 5, and 6 all contain a general factor, whereas Equations 3, 7, and 8 do not contain such a factor. Equation 3 has been discussed in the literature, as it is the basic model for the multitrait–multimethod matrix. In many cases the incorporation of a general factor seems to be important. First, the general factor can be of theoretical interest. For example, Eiting (Note 1) used musicality tests constructed in a facet design; he used a facet with musical abilities and a facet with musical materials such as melody and rhythm. The theoretical interest in this study was in the comparison of the models in Equations 3 and 4. Equation 3 implies that the correlation matrix of the musicality tests can be explained by material factors and separate factors for musical abilities, whereas Equation 4 implies that next to the material factors only one musical ability is involved. Other theoretical studies comparing models with and without a general factor can easily be conceived. Suppose tests are considered in a design with two facets of Guilford's (1967) structure-of-intellect model and that all the tests belong to the same element of the third facet, for example, memory tests for the elements of the Cartesian product of the content and product facet. A point of theoretical interest in this case is the comparison of models with and without a general memory factor. Second, the comparison of models with and without a general factor is important from the point of view of test construction. For items constructed in a facet design that fit a model with a general factor, it makes sense to combine items in a total score measuring the general aspect of the construct; items that do not fit a model with a general factor should only be combined in subtest scores. Regarding the general factor, it cannot be stated a priori that this factor should be correlated or uncorrelated with other factors; this depends on the research problem or can be investigated empirically. In test-construction, it is generally useful to postulate that the general factor is uncorrelated with the other factors. But in a theoretical study, such as in the above-mentioned structure-of-intelligence tests, it can be of interest to study the correlation of a general factor with other factors.

Estimation, Testing, and Identification

If in a sample an unbiased estimate $\hat{\mathbf{S}}$ of the covariance matrix is obtained, the parameters can be estimated using the generalized least squares or the maximum-likelihood method. By assuming that the observed scores on the instrument have a multivariate normal distribution for both methods, statistics can be computed that are asymptotically distributed as chi-squares (Jöreskog & Goldberger, 1972). The chi-square value can be used for testing the goodness of fit of a model against the very broad alternative that $\mathbf{S}$ is any positive, de-

Table 2
Means, Standard Deviations, and K-R 20 Reliability Coefficients for 5-Item Tests Measuring Social Anxiety in Children

Test	*M*	*SD*	K-R 20

Appearance–affective	1.63	1.29	.46

Note. K-R 20 = Kuder-Richardson formula. For *M*s and *SD*s, $N = 320$; for K-R 20, $N = 396$: The group of 320 subjects was increased with the addition of 76 third-grade students.

definite matrix (Jöreskog, 1974). Moreover, different models can be compared by the right-tail probabilities of their chi-square values. Also, a Model M_1, nested in Model M_2, can be tested against Model M_2: The difference in chi-square values is asymptotically a chi-square with degrees of freedom equal to the difference of the degrees of freedom of the models. Model M_1 is said to be nested in M_2 if M_1 can be obtained from M_2 by constraining one or more of the free parameters in M_2 to be fixed or to be equal to one another (Long, 1976). Another method for the investigation of the fit of a model is the inspection of the matrix with the residual covariances:

$$\mathbf{R} = \hat{\mathbf{S}} - (\hat{\mathbf{L}}\hat{\mathbf{C}}\hat{\mathbf{L}}' + \hat{\mathbf{E}}^2), \qquad (13)$$

where $\hat{\mathbf{L}}$, $\hat{\mathbf{C}}$, and $\hat{\mathbf{E}}^2$ are the estimates for the matrices $\mathbf{L}$, $\mathbf{C}$, and $\mathbf{E}^2$. The computations can be done with the computer programs ACOVS (Jöreskog, Gruvaeus, & Van Thillo, Note 2) and LISREL (Jöreskog & Van Thillo, Note 3; Saris, Note 4).

A model is said to be identified if all parameters are uniquely determined. For example, the factor analytic model is not identified; the parameters are not unique, and the factor solution can be rotated. A necessary condition for identification is that the number of distinct parameters in the covariance matrix $\mathbf{S}$ be at least as high as the number of parameters implying that the number degrees of freedom must be equal to or greater than zero. This condition is necessary but not sufficient. A second condition is that the linear equations in the model be such that each individual parameter can be separated from the other parameters. In general it is hard to investigate this condition. Moreover, it is possible that the condition may be fulfilled but the model still not identified. This can happen if the estimate of a parameter in a sample is about zero (Saris, Note 4). A practical procedure for investigating the identifiability of a model is to ask for the standard errors of the parameter estimates. If the program can compute the standard errors, one has good assurance as to the identifiability of the model (Wiley, 1973). Another practical procedure is to estimate the parameters twice by starting the computing procedure with different initial values for the parameters. If the estimates of the parameters for both computer runs are equal, one also has good assurance as to the identifiability of the model (Saris, Note 4).

Measurement of Social Anxiety in Children

Dekking and Raadsheer (Note 5) used a situational and a behavioral facet for the construct of social anxiety in children. In the situational facet five types of situation in which children can exhibit social anxiety were differentiated: social, intellectual, physical, exclusion, and appearance. In the behavioral facet four types of reaction indicating social anxiety were differentiated: cognitive, avoidance, physiological, and affective. The Cartesian product of the two facets has 20 elements (see Table 1); for each element 5 items were written. An example of a social–avoidance item is as follows: "During recreation I don't play with other children" (yes/no); an example of an appearance–cognitive item is as follows: "Having had a hair cut I am afraid others think I look strange" (yes/no). The 100

items were administered to 320 children from the fourth, fifth, and sixth grades of three elementary schools. Each item was scored 1 (indicating social anxiety) or 0 (indicating the absence of social anxiety). For every 5-item test the score was the sum of the item scores. For the 20 tests, means, standard deviations, and Kuder-Richardson formula (K-R 20) reliability coefficients of the scores were calculated (see Table 2); the correlation coefficients among the 20 variables were also calculated (see Table 3). The interest in this study was in the relations among the variables and not in the scale in which the variables are measured. It was therefore decided to analyze the correlation matrix that is the covariance matrix of the standard scores. From the means in Table 2 it is obvious that the frequency distribution of most of the variables is skewed. The assumption of a multivariate normal distribution of the observed scores is certainly not fulfilled, and goodness of fit tests should therefore be interpreted very carefully. It is assumed that the population covariances of the residuals of the instruments are zero; therefore, in all the analyses $\mathbf{E}^2$ is a diagonal matrix with the residual variances on the diagonal.

The variance component model (Equation 9) is the model with the smallest number of parameters. Hence the analysis was started with this model; the form of Equation 11 is presented in Table 4. From the assumption that the population covariances of all latent variables are zero, it follows that in Equation 12 $\mathbf{C}$ is a diagonal matrix with diagonal elements: var (S), var (R_1), var (R_2), var (R_3), var (R_4), var (R_5), var (C_1), var (C_2), var (C_3), and var (C_4). Matrix $\mathbf{L}$ is not of full column rank; therefore, constraints are necessary for estimating the variance components (Jöreskog, 1974). In this stage of the investigation, however, interest was not in estimating the parameters but in fitting a model. The unconstrained model was therefore fitted to the data. The value of the chi-square for this model is 547.39 with 181 degrees of freedom; the fit of the variance component model is very poor.

In Equation 11 the variances of the latent variables of the vector $\mathbf{f}_i$ were subsequently set equal to one. The matrix $\mathbf{L}$ is then a matrix with loadings: The ones in the matrix $\mathbf{L}$ in Table 4 are replaced by parameters that should be estimated. In this case Equation 12 gives the structure of the covariance matrix of the observed scores in a restricted factor model

with one general factor, five situation factors, and four reaction factors. From the assumption that the factors are orthogonal, it follows that the matrix **C** in Equation 12 is an identity matrix. The value of the chi-square for this model is 210.49 with 130 degrees of freedom. Comparing the statistics of both models shows that the fit of the factor analytic model is better than the fit of the variance component model. Inspection of the matrix **R** shows that residual correlation coefficients higher than .10 or lower than −.10 are between the following variables: social–avoidance and physical–cognitive (.113), social–avoidance and physical–avoidance (.131), social–avoidance and physical–affective (.166), social–affective and exclusion–avoidance (.117), intellectual–avoidance and physical–affective (.137), and physical–affective and appearance–physiological (−.108). In five of the six cases, tests measuring avoidance reactions are involved. Moreover, from Table 2 it is clear that the tests measuring avoidance reactions generally show low K-R 20 reliability coefficients. Therefore, the five tests measuring avoidance reactions were eliminated from the correlation matrix, the avoidance-reaction factor was also eliminated, and the revised data were reanalyzed. The resulting chi-square value is 99.59 with 60 degrees of freedom. However, the standard errors of the parameters could not be computed, indicating that the model is not identified. Inspection of the parameter estimates showed that the loading of social–cognitive on the factor Social and the loading of exclusion–affective on the factor Exclusion are both near zero. To obtain an identified solution these two loadings were constrained to be equal to each other. In the computing procedure we encountered serious difficulties: In the iteration process the loading of social–affective on the factor Affective became larger and larger than one, while the residual variance became smaller and smaller than zero. It was therefore decided to stop the iteration process. A cause for difficulties in obtaining an identified model can be that all factors are specified to be uncorrelated. Therefore, it was assumed that the situation factors are correlated between one another and that the reaction factors are correlated between one another; the correlations between situation and reaction factors and between the situation and reaction factors on the one hand and the general factor on the other are assumed to be zero. The fit of this model is excellent: The value of the chi-square is 33.57 with 47 degrees of freedom; the range of the coefficients of **R** is from −.047 to .050. The program computes standard errors of the parameter estimates, indicating that the model

Note. $N = 320$.

is identified. Table 5 gives the symmetrical 90% confidence intervals for the loading estimates, and Table 6 gives the confidence intervals for the factor correlation estimates. The confidence intervals for the correlations between the factor Intellectual and the other situation factors are inadmissibly large. The concept of the specific factor Intellectual is not very appropriate for the description of the correlation matrix. The use of a general factor, uncorrelated with all other factors, seems appropriate: 10 instruments have substantial loadings on this factor. Also, it seems appropriate to distinguish the factors Social, Physical, Exclusion, and Appearance. The factor Social is correlated with the other three factors: The intervals for the correlations do not contain the value zero; the intervals also do not contain the value one, indicating that it makes sense to distinguish the factor Social from the other three factors. The intervals of the intercorrelations of the factors Physical, Exclusion, and Appearance all contain the value zero. Moreover, almost all loadings on these four situation factors are substantial. There is, however, not much reason to distinguish the reaction factors: The intervals of the intercorrelations of these three factors all contain the value one.

Discussion

The analysis of the social anxiety data has shown that covariance structure analysis can be an important tool in test construction. To construct an instrument for measuring general social anxiety, one can select and combine tests with high loadings on the general factor. It is also possible to construct composite instruments that measure special aspects of social anxiety. For example, a composite of the tests physical–physiological, and physical–affective, and physical–cognitive would constitute an instrument that measures social anxiety in physical situations.

The question of why covariance structure analysis should be used for the analysis of correlation matrices from facet designs can be raised. Conventional factor analytic methods, especially three-mode factor analysis (Tucker, 1963), could also be used. Some points are mentioned briefly. First, conventional factor analytic methods are mostly used for exploring the structure of a correlation matrix, whereas covariance structure analysis is appropriate for testing hypotheses about matrices. Second, in covariance structure analysis the parameters can be estimated with the maximum-likelihood method. This implies that the properties of the estimates are known; the desirable properties of maximum-likelihood estimates are described by Mood and Graybill (1963, p. 185). Moreover, from the standard errors of the parameter estimates, confidence intervals can be derived. The properties of the estimates in conventional factor analytic methods are not known, and it is also not possible to specify confidence intervals. Third, it should be emphasized that it is assumed that the observed scores have a multivariate normal distribution. In applications this assumption is sometimes even not approximately fulfilled, and the effect of this is not known. Finally, it should also be emphasized that there are many problems in the use of covariance structure analysis. To men-

tion some, it is sometimes hard to formulate hypotheses and identifiable models, the computing time can be high, some problems, such as the power of the test of a model, are not resolved, and the variables must be quantitative and their relations linear.

The model with 10 factors proved to be an adequate explanation for the correlation coefficients between the 15 social anxiety variables. This does not mean, however, that it is the only model that fits the data. For the correlation matrix of the 20 variables, for example, the following model was used: five situation factors, four reaction factors, and two correlated second-order factors, one a general situation factor and the other a general reaction factor. Each test has a loading on one situation and on one reaction factor; each situation factor has a loading on the general situation factor, and each reaction factor has a loading on the general reaction factor. The model is a restricted, second-order factor analysis model (Jöreskog, 1974). The total number of parameters in this model is one less than in the model with the 10 orthogonal, first-order factors. The value of the chi-square for this model is 207.16 with 131 degrees of freedom; the fit of the model is about the same as the model with the 10 orthogonal, first-order factors. Inspection of the matrix **R** shows that the coefficients higher than .10 or lower than −.10 are between the following variables: physical–cognitive and social–avoidance (.116), physical–avoidance and social–avoidance (.138), physical–affective and social–avoidance (.136), physical–avoidance and social–affective (−.108), physical–affective and intellectual–affective (−.111), exclusion–affective and physical–cognitive (.112), appearance–avoidance and physical–cognitive (.109), physical–cognitive and appearance–affective (.105), and physical–affective and appearance–physiological (−.135). Although the picture is not as clear as in the previous analysis, it is likely that elimination of some tests can improve the fit of the model. This was not done because a model with two correlated second-order factors is more difficult to interpret than a model with first-order factors.

It has already been stated that the general model in Equation 2 can easily be generalized to more than two facets. For example, the model for the score of Subject i on the combination of the jth element of the first facet, the kth element of the second facet, and the lth element of the third facet is

$$y_{ijkl} = m_{jkl} + s_{jkl}S_i + r_{jkl}R_{ij} + c_{jkl}C_{ik} + h_{jkl}H_{il} + rc_{jkl}RC_{ijk} + rh_{jkl}RH_{ijl} + ch_{jkl}CH_{ikl} + E_{ijkl}. \quad (14)$$

From this equation it can be seen that the number of parameters is very large; restrictions in the model are necessary.

Models for Biases in Judging Sensory Magnitude

E. C. Poulton
Medical Research Council, Applied Psychology Unit
Cambridge, England

Category ratings and magnitude judgments are affected by four range biases, the centering bias, the stimulus and response equalizing biases, and the contraction bias; by three nonlinear biases, the local contraction bias, the stimulus spacing bias, and the logarithmic bias; and by bias from transfer. Models of the biases are described. The biases are most marked in sensory dimensions that students are not taught to handle, such as loudness and brightness. Avoiding all the biases requires exceedingly rigorous investigations.

Why Sensory Magnitudes

Sensory magnitudes are selected for this review of biases in judgment because the stimuli can be measured on a physical scale. Judgments of the quality of life or of the likableness of people lack a precise measure of the stimulus. Thus the biases are more difficult to specify exactly. Anderson (1974), Helson (1964), Parducci (1963), and the late S. S. Stevens (1975) all use sensory magnitudes when presenting their theories of judgment.

Kinds of Stimuli

Averaging two weights and multiplying two lengths to calculate the area of a rectangle are a part of common knowledge. Students can handle these problems with relatively little bias (Anderson, 1974, Figures 1 and 8) because they are taught models of the way the sensory dimensions work.

Common knowledge does not include averaging two sound intensities or two light intensities, which is usually described as bisecting the interval between the two intensities. Nor does common knowledge include halving and doubling loudnesses and brightnesses. Judgments of these unfamiliar kinds are more easily biased. They are therefore the judgments to use in studying biases.

Kinds of Responses

Responses that are closely linked to the stimuli by well-known rules are less easy to bias than responses that are only loosely related. The display that follows lists the kinds of responses that are asked for in studying judgments of sensory magnitude. They are ordered by the extent to which they are linked closely to the stimuli by well-known rules:

Familiar physical units
Named categories
Numbered categories
Numbers
Cross-modal matches

First is a familiar physical measure of the stimulus such as length in meters. Provided the observer is given an adequate opportunity to study the stimulus, these responses are not easily biased except by the contraction bias. Next are rating scales with named or numbered categories. Finally, there are the numerical magnitude judgments and the cross-modal matching responses advocated by

The author is grateful to R. F. Fagot and R. Teghtsoonian for permission to make use of their unpublished information, to R. D. Patterson for commenting on a draft of the article, and to the British Medical Research Council for financial support.

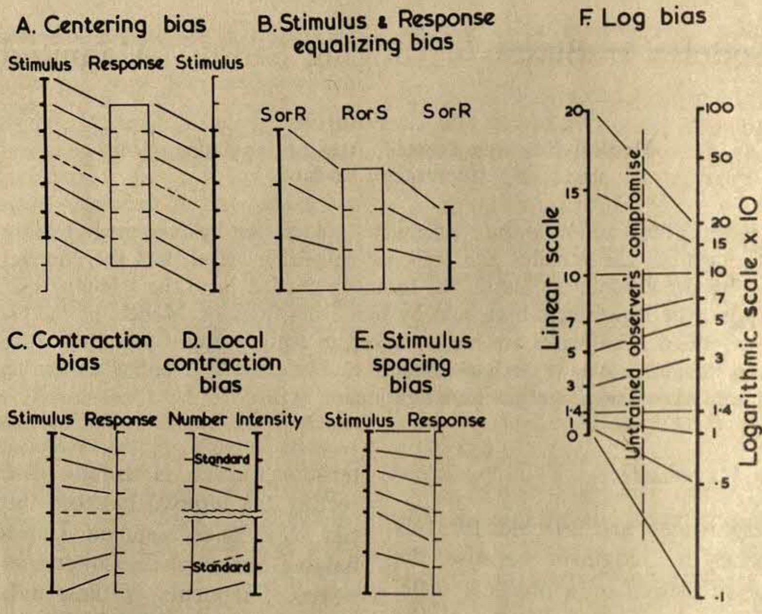

Figure 1. Models for the biases in judging sensory magnitudes; Models A, B, and C are concerned with the overall range, whereas Models D, E, and F are concerned with the nonlinearities within the overall range. (S = stimulus; R = response.)

S. S. Stevens (1975). Ratings and magnitude judgments are all relatively easily biased.

It is assumed in the display that the investigator selects the physical stimuli and that the observer gives one of the kinds of responses mentioned. But there is an alternative type of investigation in which the investigator gives one of the kinds of responses and the observer sets the size of the physical stimulus to match it. Both types of investigation can be biased in similar ways.

Kinds of Bias

In the centering bias of Figure 1A, the observer centers his range of responses on the range of stimuli. In the stimulus spacing bias of Figure 1E, the observer responds as if all the stimuli were equally spaced geometrically and equally probable. Parducci (1963; Parducci & Perrett, 1971) describes the effect of these two biases together by his range–frequency model. The model extends and modifies Helson's (1964) original adaptation-level model of the two biases.

The contraction bias of Figure 1C is a general characteristic of human behavior. It affects the distances reproduced by a limb as well as the judgments of anything that can be quantified, such as overt judgments of sensory magnitude (Poulton, 1973, 1974, 1975). Large stimuli and differences between stimuli are underestimated, whereas small stimuli and differences are overestimated. Once the observer knows the range of responses, he selects a response too close to the middle of the range. S. S. Stevens and Greenbaum (1966) call the contraction bias the "regression effect."

The local contraction bias of Figure 1D appears to have been described only for judgments of loudness. Acoustic stimuli in small, very high-intensity and very low-intensity ranges are treated as if they had less extreme values than they do have. This corresponds to the time–order error in investigations of the differential threshold (Hollingworth, 1910; Woodworth, 1938, pp. 438–448).

Judgments of sensory magnitude are affected also by the stimulus and response equalizing biases of Figure 1B. For the stimulus equalizing bias, the two scales at the sides represent stimuli, whereas the scale

in the middle represents responses. The observer uses his full range of responses whatever the size of the range of stimuli. For the response equalizing bias, the two scales at the sides represent responses, whereas the scale in the middle represents stimuli. The observer uses a larger range of responses when he is provided with a larger range.

Numerical judgments that require a step change in the number of digits are affected also by the logarithmic bias of Figure 1F. In using numbers logarithmically, the observer treats 1-, 2-, 3-, . . . , *n*-digit numbers as equally frequent instead of treating *n*-digit numbers as 10 times as frequent as (*n* − 1)-digit numbers. This shrinks the upper part of the numerical scale (Banks & Hill, 1974).

The logarithmic bias, the two contraction biases, and the stimulus and response equalizing biases can all affect the observer's very first judgment. In contrast, the effects of the centering bias and the stimulus spacing bias come on gradually as the observer learns the set of stimuli. These last two kinds of bias can both be said to be due to transfer from previous stimuli.

Judgments of sensory magnitude can be biased also by transfer from previous investigations, from instructions and demonstrations, from previous stimuli, from previous judgments, and from previous responses. The importance of the bias introduced into experiments by transfer is now becoming clear (Erlebacher, 1977; Greenwald, 1976; Poulton, 1973, 1974, 1975; Poulton & Freeman, 1966).

Centering Bias

The centering bias affects category ratings. Together with the stimulus spacing bias, it accounts for Helson's (1964) level of adaptation. Parducci (1963; Parducci & Perrett, 1971) shows that the level of adaptation depends on two characteristics of the distribution of stimuli, which can be varied independently. The influence of the midpoint of the range of stimuli is described here as the centering bias. The influence of the median of the distribution of stimuli is discussed later as the stimulus spacing bias.

Figure 1A illustrates a model of the centering bias. The stimulus intensities used in the theoretical investigation represented on the left side of the figure are two steps greater than the stimulus intensities used in the investigation represented on the right. Yet once the observer has learned the range, he centers his response scale on the range of stimulus intensities, whatever their physical values are. This is indicated by the lines that all slope down toward the right. Thus, a more intense stimulus from the investigation represented on the left side of the figure receives the same rating as a less intense stimulus from the investigation represented on the right side of the figure.

Centering Bias in Rating Noisiness

Figure 2 illustrates the centering bias in five fairly comparable investigations of the noises made by road vehicles and by aircraft. The filled points represent motor vehicle noise (from D. W. Robinson, Copeland, & Rennie, 1961). The unfilled points represent aircraft noise (from Bowsher, Johnson, & Robinson, 1966). The vertical lines show the range of noises in decibels (dB[A]). The short horizontal lines show the midpoints of the ranges. The vertical lines have been separated horizontally to make all the midpoints of the ranges lie on the dashed straight line.

The diamonds indicate the midpoints of the straight lines fitted to the ratings. This is the transition between acceptable and noisy in the D. W. Robinson et al. (1961) investigation and between moderate and noisy in the two Bowsher et al. (1966) investigations. In the Andrews and Finch (1951) and Lauber (Note 1) investigations the diamonds indicate the transition between unobjectionable or inoffensive and objectionable or annoying.

If the observers were to behave like sound level meters and have a fixed criterion for the just acceptable level of noise, all the diamonds in Figure 2 would lie on a horizontal line. If the ratings were determined entirely by the midpoints of the ranges of sounds presented, the diamonds would be superimposed upon the short horizontal lines.

Table 1
Avoiding Biases

Bias	Avoiding bias in category rating	Avoiding bias in magnitude estimation
	Range biases	
Centering (Figure 1A) The observer centers his range of responses on the range of stimuli	Use only the set of responses that has a demonstrably unbiased center, or Ask for only a single judgment	Ask for only a single judgment
Stimulus equalizing (Figure 1B) Whatever the size of the stimulus range, the observer uses his full range of responses	Unavoidable	Use a stimulus dimension of the same subjective size as the response dimension
Response equalizing (Figure 1B) Whatever size of response range the observer is given, he distributes the responses over the stimulus range	Unavoidable	Use a response dimension of the same subjective size as the stimulus dimension
Contraction (Figure 1C) The observer underestimates large stimuli and differences between stimuli and overestimates small stimuli and differences	Use only the neutral rating of the stimulus at the center of the range of named categories, or	Balance the biases by interchanging stimuli and responses and taking the average
Once the observer knows the range of responses, he selects a response too close to the middle of the range	Anchor the rating scale to the stimulus range at both ends	
	Nonlinear biases	
Local contraction (Figure 1D) The observer treats stimuli in small very high-intensity and very low-intensity ranges as if they had less extreme values		Avoid a small stimulus range with extreme values
Stimulus spacing (Figure 1E) The observer responds as if the stimuli were equally spaced geometrically and equally probable	Use equal geometric spacing and present the stimuli equally often, or Ask for only a single judgment	Use equal geometric spacing and present the stimuli equally often, or Ask for only a single judgment
Logarithmic (Figure 1F) The observer treats 1-, 2-, 3-, . . ., n-digit numbers as if they were equally frequent; this shrinks the upper part of the numerical scale	Stick to one-digit numbers	Stick to a range of numbers all having the same number of digits

Table 1 (*continued*)

Bias	Avoiding bias in category rating	Avoiding bias in magnitude estimation
	Transfer biases	
Transfer from previous investigations Transfer from instructions and demonstrations Transfer from previous stimuli Transfer from previous judgments Transfer from previous responses	Ask unpracticed observers for only a single judgment with unbiased instructions and no demonstrations	Ask unpracticed observers for only a single judgment with unbiased instructions and no demonstrations
	All biases combined	
	Ask separate groups of unpracticed observers for only a single judgment with unbiased instructions and no demonstrations; then use only the neutral rating of the stimulus at the center of the range of named categories; the stimulus and response equalizing biases are unavoidable	Ask unpracticed observers for only a single judgment with unbiased instructions and no demonstrations; also avoid a small stimulus range with extreme values and a response range with a step change in the number of digits; also use for stimuli and responses two sensory dimensions with subjectively equal-sized ranges, and balance the contraction biases by interchanging stimuli and responses for a separate group of unpracticed observers and averaging the results

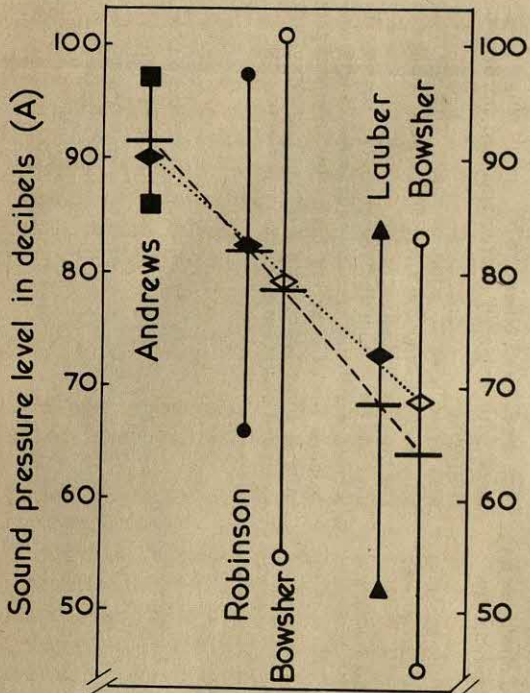

Figure 2. The centering bias in rating noises. (The vertical lines indicate the ranges of noise intensities heard. The short horizontal lines represent the midpoints of the ranges. The diamonds show the average just acceptable noise levels that lie at the midpoints of the rating scales obtained from separate groups of between 19 and 37 observers. Andrews = Andrews & Finch, 1951; Robinson = D. W. Robinson, Copeland, & Rennie, 1961; Bowsher = Bowsher, Johnson, & Robinson, 1966; and Lauber = Lauber (Note 1). Adapted from Poulton, 1977, Figure 2.)

The dotted line fitted to the diamonds by eye is a compromise, which favors the midpoints of the ranges. The midpoints of the ratings are determined less by the actual sound levels than by the ranges.

In the Andrews and Finch investigation on the left side of Figure 2, the diamond representing the midpoint of the 10-point scale of objectionableness is too high. It is pulled up by the middle of the range of noise intensities. In the investigations illustrated on the right side of the figure, the diamonds are too low. They are pulled down by the middle of the range of noise intensities. The dashed and dotted lines cross at about 85 dB (A). Here a diamond would be pulled neither up nor down. The crossover represents the only point in the data that is not affected by the centering bias.

Avoiding the Centering Bias in Ratings

A field investigator who wants to obtain named categories to represent sensory magnitudes can avoid the centering bias by using a method that provides data comparable to all the data illustrated in Figure 2. Separate groups of observers hear all the sounds, each group with a different constant amplification or attenuation. Thus, each group of observers provides a single vertical function like one of those of Figure 2. For the group whose average midrating is found to lie at the crossover point illustrated in the figure, the judgments are not affected by the centering bias. This method of avoiding the centering bias is listed at the top of the middle column of Table 1.

Table 1 indicates that the centering bias can also be avoided by restricting each group of observers to a single stimulus. If the investigator wants to measure only the just acceptable noise level at the middle of the range of ratings, separate groups of observers can each be given a single noise to judge at a different intensity. The observers have to decide simply whether the noise is acceptable or not acceptable. The noise that is judged acceptable by just 50% of the observers can then be determined. However, it is essential that the observers not have heard a range of noises of different intensities before judging their single noise. This is because their judgment will be affected by the previous stimulus range, even though they do not judge the noises (Bowsher et al., 1966, Table 3; Von Wright & Kekkinen, 1970).

Investigators who use numerical category ratings are often concerned only with the relative positions of the sensory magnitudes on the rating scale, not with their absolute positions. Here the centering bias does not matter. Often the investigator anchors the upper end of the rating scale to the most intense stimulus in his series and the lower end of the rating scale to his least intense stimulus. In doing so, he centers the rating scale on the range of stimuli.

Centering Bias in Direct Magnitude Estimation

The top of the last column of Table 1 indicates that in direct magnitude estimation, the centering bias can also be avoided by asking each observer for a single judgment. However, in using direct magnitude estimation, the investigator generally wishes to obtain only a relative judgment between two intensities, not an absolute judgment. The relative judgment shows how the reported difference in sensation varies with the difference in intensity. S. S. Stevens (1971, 1975) uses the following model:

$$\psi = K\,\phi^n,$$

or taking logs,

$$\log \psi = \log K + n \log \phi,$$

where ψ is the subjective intensity and ϕ is the physical intensity. In this model the centering bias is represented by log K. It is equated across observers or investigations by fixing or adjusting the value of K.

Logarithmic Bias

The Arabic numbering system introduces a logarithmic bias into the observer's use of numbers when he reaches a step change in the number of digits. After counting up to 10 the observer has two alternatives for the way in which to proceed. He can behave linearly and continue 11, 12, 13, . . . , or he can be more logarithmic and continue 20, 30, 40, ...

If the observer generates numbers linearly, he uses two-digit numbers 10 times as often as single-digit numbers. He uses three-digit numbers 100 times as often, and so on. If the observer generates numbers logarithmically, he uses 1-, 2-, 3-, . . . , n-digit numbers equally often. This shrinks the upper part of the response scale, as illustrated on the right side of Figure 1F.

The numbers generated can be arranged in rank order of size at equal intervals along the abscissa of a graph. When the numbers are plotted with a linear scale on the ordinate, the function is markedly concave upward, whereas when the scale on the ordinate is logarithmic, the function is slightly concave downward. The untrained observer compromises between pure linear and pure logarithmic choices, but favors logarithmic choices (Banks & Hill, 1974).

Figure 1F shows the relationship between numbers plotted logarithmically and numbers plotted linearly. The two sets of numbers are scaled so that they are the same height at 10 and at 1.4 on the two scales. At these two points,

$$x = 10 \log_{10} x.$$

At other points, the corresponding numbers are not the same height because here x and $10 \log_{10} x$ are different.

The lines connect various xs on the linear scale to the corresponding $10 \log_{10} x$s on the logarithmic scale. Between 3 and 7 the lines are almost parallel, so the two scales are virtually identical. Above 7 the logarithmic scale shrinks compared with the linear scale, while below 3 it expands compared with the linear scale. But when observers generate numbers in an experiment, the variability is so large that it is usually not possible to distinguish reliably between the two numbering systems in the range between 1 and 10.

The figure shows that above 10 the logarithmic scale is very much more condensed than the linear scale. So when an observer generates numbers that extend from 1 or 2 up to 50 or 100, it is possible to determine whether he is behaving linearly or logarithmically. The broken vertical line in Figure 1F indicates that in generating numbers, the unpracticed observer compromises between the two scales.

Numbers below 1.0 are rarely used in psychophysical investigations. Here the logarithmic scale is very much more spread out than the linear scale. This explains why when sensory magnitude is plotted with a logarithmic scale on the ordinate of a graph against physical magnitude on the abscissa, the slope of any psychophysical function becomes steeper as the threshold is approached. The threshold represents zero sensory magnitude. On the logarithmic scale of the ordinate, the threshold is infinitely far away in a downward direction (Poulton, 1968, p. 5).

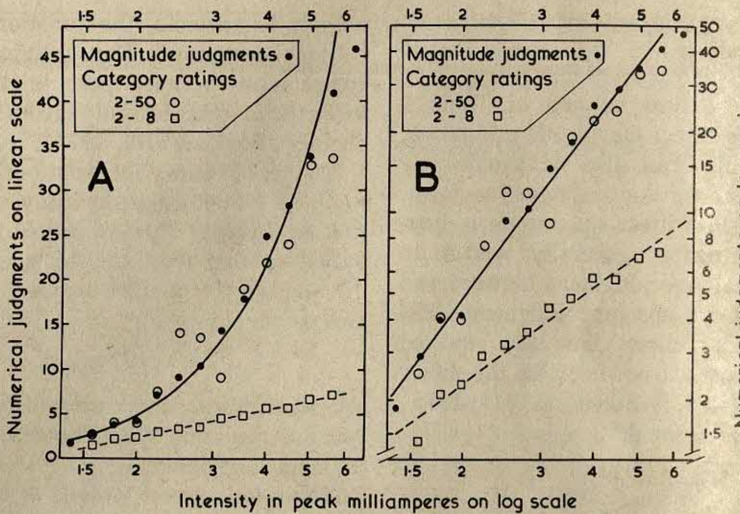

Figure 3. The logarithmic bias in direct magnitude estimation of electrotactile stimuli and in rating the stimuli on a 49-point scale corresponding to the average range of numbers used in the magnitude estimation. (Ratings using 7 categories are also shown. Panel A has a linear scale on the ordinate, whereas Panel B has a logarithmic scale. Results are from Gibson & Tomko, 1972.)

Logarithmic Bias in Rating

Figures 3A and 3B (results of study by Gibson & Tomko, 1972) illustrate the logarithmic bias that occurs when an observer rates electrotactile intensity with a large number of numerical categories. The numerical judgments on the ordinate are plotted in Figure 3A with a linear scale and in Figure 3B with a logarithmic scale. Thus, the solid straight line of Figure 3B becomes the solid line that is concave upward in Figure 3A. The electrotactile stimuli on the abscissa have the same logarithmic scale in both figures.

The unfilled circles represent the arithmetic means of a group of 11 observers who use a rating scale with 49 main categories. The categories 1 and 51 are reserved for stimuli judged to fall outside the initially defined range of stimuli. With the linear vertical scale of Figure 3A, the function represented by the unfilled circles is markedly concave upward, whereas with the logarithmic vertical scale of Figure 3B, the function is slightly concave downward. The slight downward concavity is indicated by the unfilled circles at the top and bottom of the function, which lie below the solid straight

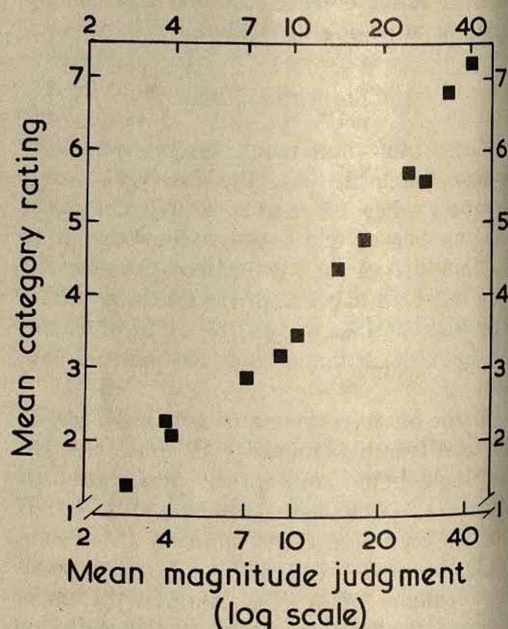

Figure 4. Mean 7-point category ratings plotted on a linear scale against mean magnitude judgments plotted on a logarithmic scale. (The two sets of data are from two separate groups of 11 observers. The function is slightly concave upward because the magnitude judgments are plotted on the appropriate logarithmic scale instead of on a linear scale. Results are from Gibson & Tomko, 1972.)

line. The slight downward concavity shows that the observers do not use a purely logarithmic numbering system, although their hybrid numbering system is nearly logarithmic.

The logarithmic bias does not affect ratings with 9 or less numerical categories (Montgomery, 1975; Parducci, 1963). The squares and the dashed fitted straight lines in Figures 3A and 3B represent the arithmetic means of a separate group of 11 observers who use a rating scale with 7 main categories. The categories 1 and 9 are reserved for stimuli judged to fall outside the initially defined range of stimuli. With the linear vertical scale of Figure 3A, the function represented by the squares is closely fitted by the straight line. Thus the logarithmic bias affects the rating scale with 49 categories but not the rating scale with 7 categories.

S. S. Stevens (1975, Figure 50) reports a logarithmic bias in ratings of loudness using seven categories. But this is presumably caused by transfer of the logarithmic bias from previous investigations on magnitude estimation performed by the same observers. Transfer between S. S. Stevens's various investigations is discussed later in this review.

With the logarithmic vertical scale of Figure 3B, the squares are also fitted fairly well by the straight line. This is because Figure 1F shows that within the range between 1 and 10, the linear and logarithmic scales are reasonably comparable. The most deviant square in Figure 3B is on the extreme left, with a mean rating as low as 1.4. Here Figure 1F shows that the two scales begin to differ appreciably.

Logarithmic Bias in Direct Magnitude Estimation

The filled circles and fitted solid line in Figure 3B illustrate the logarithmic bias in direct magnitude estimation. Here the points represent geometric means instead of arithmetic means. The results are from another separate group of 11 observers who judge the stimulus intensities in numbers without a specified standard or modulus. In Figure 3B the function represented by the filled circles is slightly concave downward, like the function represented by the unfilled circles for the ratings. The slight downward concavity shows that the observers do not use a purely logarithmic numbering system. However the filled circles in Figure 3A show that the observers certainly do not use a linear numbering system.

When the magnitude judgments of Figures 3A and 3B are plotted against the category ratings on the 49-point scale represented by the unfilled circles, the resulting function is a straight line (Gibson & Tomko, 1972, Figure 4). This indicates that the logarithmic bias affects magnitude judgments and category ratings to a similar extent, provided the range of numbers used as responses is about the same. In Gibson and Tomko's experiment, the numbers used for the category ratings are selected to correspond to the average range of numbers used in the magnitude judgments. It follows that the difference between direct magnitude estimation by unpracticed observers and numerical category rating is simply in the range of numbers normally used, not in the kind of judgment that the observers are instructed to make. Montgomery (1975, Figure 1, Panels A_1, A_2, and A_3) makes a similar point.

Ratings and Magnitude Estimates

The same stimuli can be judged while using either a linear numbering system or a logarithmic numbering system. When the two sets of judgments are plotted against each other with the linear scale on the ordinate and the logarithmic scale on the abscissa, the resulting function should be a straight line. But as Torgerson (1960) points out, the function is usually slightly concave upward, like the function in Figure 4. The figure shows Gibson and Tomko's (1972) 7-point ratings plotted on a linear scale against their magnitude judgments plotted on a logarithmic scale. The function is slightly concave upward because Figures 3A and 3B show that the ratings use a linear numbering system, whereas the magnitude judgments have a logarithmic bias, but are not completely logarithmic.

Torgerson's (1960, Figures 3 and 4) re-

sults for Munsell grays and Eisler's (1962, Figure 4, Panels ILa, IILa, IIILa, ISa, IISa, and IIISa) and Montgomery's (1975, Table 2) results for loudness all give functions that are slightly concave upward, like the function in Figure 4. Where the stimulus spacing does not bias the shape of the functions, Montgomery's results are clearly due to the hybrid numbering system used for the magnitude judgments, as with the data of Figure 4. Unfortunately Torgerson's and Eisler's results are influenced by the stimulus spacing bias and perhaps also by transfer from previous magnitude judgments or category ratings. Transfer bias from previous conditions is not possible in Gibson and Tomko's and Montgomery's experiments because they use a separate group of observers for each condition.

Figure 3A shows that Gibson and Tomko's (1972) 7-point ratings are linear on a lognormal or semilog plot. Thus in physical units, the equal intervals between the ratings on the ordinate of Figure 4 correspond to a logarithmic physical scale. The logarithmic scale of the magnitude judgments on the abscissa of Figure 4 also corresponds more or less to a logarithmic physical scale. This is because Figure 3B shows that the relationship between the magnitude judgments and the physical units is almost a straight line on a loglog plot. So both the vertical and the horizontal scales of Figure 4 are more or less equivalent to the logarithm of the physical units, hence the more or less straight-line relationship between them in the figure.

It is important to distinguish between the slightly concave upward relationship of Figure 4 and the markedly concave downward relationship reported by S. S. Stevens and Galanter (1957, Figures 8 and 9) between category and direct magnitude scales of loudness. S. S. Stevens and Galanter plot the logarithmic ratio judgments using a linear scale of sones instead of a logarithmic scale. This converts the slightly concave upward relationship of Figure 4 into S. S. Stevens's well publicized concave downward relationship (Eisler, 1962, Figure 4, Panels ILb, IILb, IIILb, ISb, IISb, and IIISb; Gibson & Tomko, 1972, Figure 3; Torgerson, 1960, Figure 3.1). The concave downward relationship is produced simply by plotting what corresponds to a logarithmic physical scale on the ordinate against what corresponds to a linear physical scale on the abscissa. It has no greater significance than this.

Avoiding Hybrid Numbering Systems

The logarithmic bias is most likely to occur when the observer uses a range of numbers that includes a step change in the number of digits. In S. S. Stevens's method of direct magnitude estimation, a stimulus in the middle of the range of stimuli may be called 10. The observer has then to use both one-digit and two-digit numbers. If the observer serves in several such investigations, the logarithmic bias in using numbers greater than 10 is likely to transfer to the use of numbers between 1 and 10. Eventually the observer may consistently use numbers logarithmically. Differences between sensory intensities are then expressed as numerical ratios. The consistent use of a purely logarithmic numbering system can be encouraged by instructing the observer to use ratios, as S. S. Stevens (1971, p. 428) does. Those who do not give ratios consistently are not invited to serve as observers.

The logarithmic bias should not occur when the observer uses numbers that all have an equal number of digits, except as a result of transfer from prior ratio judgments. The methods of avoiding the logarithmic bias are listed at the bottom of the second section of Table 1.

Stimulus Spacing Bias

The stimulus spacing bias is one of the two biases that together account for Helson's (1964) level of adaptation (Parducci, 1963; Parducci & Perrett, 1971), the other being the centering bias, which has already been discussed. Figure 1E illustrates a model of the stimulus spacing bias. The five stimuli at the top of the range of intensities on the left are spaced at geometric intervals only half the size of the three stimuli at the bottom of the range. In judging the stimuli,

the observer uses their rank order of magnitude rather than their relative subjective sizes. He behaves as if all the stimuli were subjectively equally spaced. In category rating this means using all the categories equally often. Thus the smaller intervals are overestimated compared with the larger intervals.

The *stimulus frequency bias* is a special case of the stimulus spacing bias. The observer behaves as if all the stimuli were equally probable. When one stimulus is presented more frequently than the remainder, the observer treats the more frequent stimuli as if they were all nearly, but not exactly, the same size. Thus, three identical stimuli one quarter of the way from the top of the stimulus range are treated as three closely spaced stimuli of slightly different size, as illustrated in Figure 1E. In judging all the stimuli while using their rank order of magnitude rather than their relative subjective sizes, the observer allocates an excessive amount of his response scale to the identical stimuli. The stimulus region around the identical stimuli is therefore overestimated compared with the remainder of the stimulus range.

Stimulus Frequency Bias in Rating

The stimulus frequency bias in category rating is described at length by Parducci (1963; Parducci & Perrett, 1971), who uses separate groups of observers for each condition and by Pollack (1964a, 1965a, 1965b), who uses the same or different observers. A number of extra stimuli of one particular intensity are added to a set of stimuli. The observer tends to use all his response categories equally often. Thus stimuli a little greater than the added stimuli receive higher ratings than previously, whereas stimuli a little smaller than the added stimuli receive lower ratings than previously. In the rating scale the added stimuli produce a local expansion, which is flanked on both sides by a compensatory contraction.

Stimulus Spacing Bias in Rating

An example of the stimulus spacing bias that corresponds to the model of Figure 1E

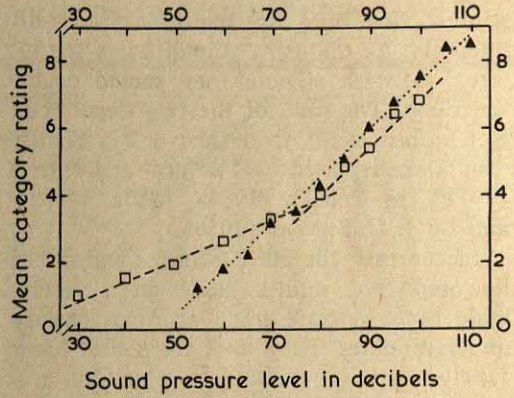

Figure 5. The stimulus spacing bias in rating the loudness of white noise. (Results are from Montgomery, 1975.)

is illustrated on the lognormal or semilog plot of Figure 5 (results from Montgomery, 1975). The unfilled squares represent ratings of the loudness of white noise made on a 7-point scale by 10 psychology undergraduates. The stimuli are spaced at 10-dB intervals between 30 and 100 dB (SPL), with additional stimuli inserted at 85 and 95 dB. The two inserted stimuli increase the slope of the function at the top end. The six points at 10-dB intervals are fitted by a separate

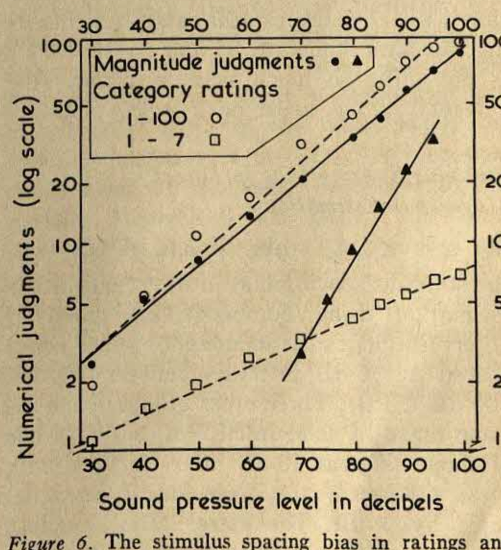

Figure 6. The stimulus spacing bias in ratings and direct magnitude judgments of the loudness of white noise. (The difference in slope between the filled triangles and the filled circles is produced by the stimulus equalizing bias. Results are from Montgomery, 1975.)

straight line from the five points at 5-dB intervals. As the extra stimuli halve the interval between stimuli, they should double the slope. The ratio of the two slopes is in fact rather larger than this: 1:2.3. Similar results are reported by Parducci and Perrett (1971), by Pollack (1964a, 1965a, 1965b), and by J. C. Stevens (1958).

In contrast, the filled triangles and dotted line represent ratings made on a 9-point scale by a separate group of 10 psychology undergraduates. They show the almost linear function that is produced by a uniform geometric spacing between all stimuli.

The unfilled squares and dashed fitted line of the loglog plot of Figure 6 (results from Montgomery, 1975) correspond to the unfilled squares and dashed fitted lines in Figure 5. Figure 6 shows that the discontinuity in the function of Figure 5 disappears when the ratings are plotted on a logarithmic scale. Inserting the extra stimuli between the stimuli at the top of the range helps to make the category ratings linear on a loglog plot like that of Figure 6.

The unfilled circles and dashed fitted line in Figure 6 are for category ratings between 1 and 100 made by another group of 10 psychology undergraduates. They show that with as many as 100 categories, inserting the extra stimuli at 85 and 95 dB (SPL) is not quite so much help in making the category ratings linear on a loglog plot.

Stimulus Spacing Bias in Direct Magnitude Estimation

J. C. Stevens (1958, Figure 3) describes the stimulus spacing bias in direct magnitude estimation using numbers. One group of observers judges the loudness of white noises spaced at 10-dB intervals between 40 and 100 dB (SPL). Three other groups judge the same range of noise intensities, but with one of three different 10-dB intervals filled with three or four extra noise intensities separated by 2 dB. The extra stimuli produce local increases in the steepness of the psychophysical function relating loudness to intensity on a loglog plot like that of Figure 6.

The stimulus spacing bias can be used to increase the effect of the logarithmic bias illustrated in Figure 1F. In judging sensory magnitudes, unpracticed observers produce functions on a loglog plot that are slightly concave downward, like the function represented by the filled triangles in Figure 6 (results from Montgomery, 1975) and by the filled circles in Figure 3B (Gibson & Tomko, 1972). The filled circles in Figure 6 are from a separate group of 10 psychology undergraduates who judge noises ranging from 30 to 100 dB (SPL). Here the stimuli are spaced 10 dB apart, except for additional stimuli inserted at 85 and 95 dB. The two inserted stimuli straighten out the concavity that would otherwise occur at the top end of the function.

Inserting additional stimuli near the top of the range is now a well-known procedure for obtaining a nearly straight-line function on a loglog plot with unpracticed observers (Eisler, 1962; J. C. Stevens & Tulving, 1957). This does not prove that subjective sensory intensity is a power function of physical intensity. It simply demonstrates the investigator's practical familiarity with the logarithmic and stimulus spacing biases and his skill in combining them to produce a nearly straight line on a loglog plot.

Avoiding the Stimulus Spacing Bias

The second section of Table 1 indicates that the stimulus spacing bias can be avoided by restricting each group of observers to a single judgment. A more practical alternative is to space all the stimuli geometrically and to present the stimuli equally often.

Confusions between stimuli reduce the slope of the psychophysical function at the point where the confusions occur. At the limit, where two different stimuli are always confused, the slope is zero because both stimuli receive the same average response. Local variations in slope can therefore be removed by making successive pairs of stimuli equally confusable. Following Weber's law (see Woodworth, 1938, pp. 430–438), this means using geometric spacing of stimuli. Geometric spacing is thus the subjectively neutral spacing, which produces a straight line and avoids the stimulus spacing bias.

Geometric stimulus spacing can be used in both category rating and in magnitude estimation. In category rating with not more than about nine categories, it produces approximately equally spaced ratings. In magnitude estimation by observers who are trained to use numbers logarithmically, it produces approximately equal subjective ratios, which are equally spaced on a logarithmic plot.

Contraction Biases

Figure 1C illustrates a model for the contraction bias. Large stimuli and differences between stimuli are underestimated, while small stimuli and differences between stimuli are overestimated. The contraction bias affects an observer's very first judgment, because he always has some idea of the range of stimuli or stimulus differences to expect.

The contraction bias is facilitated by giving the observer a limited set of responses to use with an obvious middle value. Examples are a set of ratings, the finite set of numbers used in fractional magnitude judgments, and the range of the gain control used in magnitude production and cross-modality matching. Once the observer knows the range of responses, he selects a response that is closer to the middle of the range of responses than it should be (S. S. Stevens & Poulton, 1956, Table 1).

Contraction Bias in Judging Visual Height

To investigate the contraction bias directly, it is necessary to obtain responses in the physical units used to measure the stimulus. Figure 7 illustrates the contraction bias in very first judgments of the height of a white post in a field (from Joynson, Newson, & May, 1965). The abscissa and the solid lines show the true height in inches. The points represent the mean very first judgments of five separate groups, each with 30 observers, in Experiment 1 and of four separate groups, each with 18 observers, in Experiment 2. On the left of the figure, the heights of short posts are overestimated. On the right, the heights of tall posts are underestimated. As in Figure 2, the only unbiased points are where the lines cross.

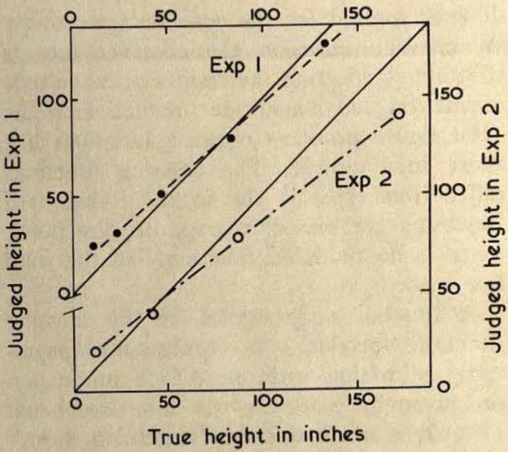

Figure 7. The contraction bias in the very first judgments of the height of a white post in a field. (One third of the observers in each group judge their post at a distance of 25 m, one third at 100 m, and the remaining third at 400 m in Experiment 1 and at 230 m in Experiment 2. Results are from Joynson, Newson, & May, 1965.)

Experiment 1 is carried out on an airfield. The dashed line fitted to the filled points crosses the solid line at a height of 80 inches (2 m). This is about the height of the perimeter fence around most airfields. Experiment 2 is carried out on a level field of mown grass. The fitted dashed line crosses the solid line at a height of 48 inches (1.2 m). This is close to the mean height of about 54 inches (1.4 m; SD = 12 inches or .3 m) given by 40 people in answer to the question, "How tall is a post?" (Joynson, Note 2). In making their very first judgments, the observers appear to take as a reference the expected height of a fence or post. They select a height a little nearer to this reference height than it should be. The reference height takes the place of the middle of the range in Figure 1C.

Contraction Biases in Direct Magnitude Estimation and Production

The contraction bias can be demonstrated indirectly by contrasting magnitude estimation with magnitude production. The difference between the two procedures is in the

dimension used for the observer's responses. Whichever dimension the observer uses is contracted. Plotting the results of magnitude estimation and magnitude production in the same figure produces crossing functions like those in Figure 7. The crossing functions differ from those in the figure in that both functions are biased in opposite directions; there is no unbiased function like the solid line in the figure.

A number of examples of the crossing functions produced by contrasting magnitude estimation with magnitude production are given by S. S. Stevens and Greenbaum (1966), who call this the "regression effect." However, in most of these investigations the two dimensions differ in size. Thus, the crossing functions are influenced by the stimulus and response equalizing biases as well as by the contraction bias. There are also transfer effects, because each observer makes a number of both kinds of judgment, each kind in a separate part of the experiment.

Sequential Contraction Bias

After the presentation of a stimulus near the top of the range of stimulus intensities, the next stimulus tends to be judged larger than it should be. After the presentation of a stimulus near the bottom of the range of intensities, the next stimulus tends to be judged smaller than it should be. This result is found in the rating of stimuli on a 10-category rating scale (Holland & Lockhead, 1968; Ward, 1972; Ward & Lockhead, 1971), in direct magnitude estimation without a standard (Cross, 1973; Jesteadt, Luce, & Green, 1977, Experiments 1 and 3), in direct magnitude estimation with a variable standard (Jesteadt et al., 1977, Experiment 2; Ward, 1973), and in cross-modal matches without a standard (Ward, 1975).

The sequential contraction bias is a special case of the contraction bias. After the presentation of a stimulus at one end of the range of stimuli, the average difference from the next stimulus selected at random is likely to be large. Large differences tend to be underestimated. Thus, the next stimulus will be judged on the average nearer than it should be to the previous stimulus. After the presentation of a stimulus near the top of the range, the bias produces a positive average constant error. After the presentation of a stimulus near the bottom of the range, the bias produces a negative average constant error. After the presentation of stimuli near the middle of the range, the average constant error is small.

When the subjective judgments are plotted against the physical stimuli, the sequential contraction bias reduces the slope of the psychophysical function. This is because after the presentation of a stimulus near the top end of the range, the stimulus with a large difference that is likely to be underestimated will be near the bottom end of the range. The size of the range is therefore underestimated. There is a similar underestimation after the presentation of a stimulus near the bottom end of the range, because the stimulus with a large difference that is likely to be underestimated will be near the top end of the range. Thus the sequential contraction bias provides the mechanism for S. S. Stevens and Greenbaum's (1966) regression effect in a series of magnitude judgments and productions (Cross, 1973).

Local Contraction Bias

In addition to the global effect of the contraction bias in direct magnitude estimation and production that has already been discussed, the contraction bias has a local effect, which is illustrated in Figure 1D. The local contraction bias corresponds to the time–order error that is found in measurements of the differential threshold (Hollingworth, 1910; Woodworth, 1938, pp. 438–448).

When presented in a small range, very high-intensity and very low-intensity stimuli are treated as if they had less extreme values. At the top of Figure 1D for a very intense standard, increasing the subjective intensity by a fixed proportion requires a smaller change in physical intensity than reducing the subjective intensity by the same proportion. At the bottom of the figure for a barely perceptible standard, the tendency is reversed. Increasing the subjective intensity by a fixed proportion requires a larger

change in physical intensity than reducing the subjective intensity by the same proportion.

As yet the local contraction bias appears to have been described only in judgments of loudness in a within-subject experimental design. The bias is illustrated in Figure 8. The figure shows the median number of decibels required to halve and double the loudness of white noise in different 10-dB ranges of sound pressure level, using the method of magnitude production (Poulton & Stevens, 1955). Each of 36 observers sets the intensity of a variable noise to what he judges to be half or double the loudness of a number of standard noises, using a volume control. He pauses for about 1.0 sec between listening to the standard noise and listening to the variable noise. In the range between 90 and 110 dB (SPL), doubling the loudness requires fewer decibels than halving does. While in the range between 30 and 50 dB, doubling requires more decibels than halving does. Over the middle range between 50 and 90 dB there is no obvious asymmetry. This corresponds to the absence of bias in the middle of the range in Figure 1D.

Two obvious explanations of the local contraction bias of Figure 8 can be rejected. Although the contraction occurs at both ends of the range, it is not due to a ceiling or floor effect from the observer approaching the end of his range of responses. At each intensity level the intensity corresponding to the standard is always about one quarter of the way from the lower end of the volume control in doubling and about one quarter of the way from the upper end in halving. Thus, there is always plenty of movement of the volume control available, with the corresponding increase or decrease in intensity.

A second obvious explanation is that the contraction bias with the ranges of intensities centered on 95 and 105 dB could be due to the observer refusing to set the intensity of his volume control high enough. Similarly the contraction bias with the ranges centered on 35 and 45 dB could be due to the observer refusing to set the intensity of his volume control low enough. However, these explanations do not account for the similar biases

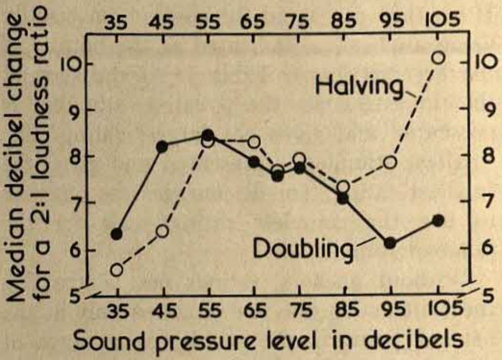

Figure 8. The local contraction bias in magnitude production with small very high-intensity and very low-intensity ranges of stimuli. (Results are from Poulton & Stevens, 1955, Figure 3.)

found with numerical magnitude estimation (S. S. Stevens, 1955b, Tables 1 and 2), because here the experimenter sets the variable sound intensities, and the observer simply judges how much louder or softer they are than the standard.

A local contraction bias similar to the dashed line of Figure 8 for halving loudness is reported by Warren (1970, 1973) for very first judgments of half loudness, for both white noise (Warren, 1973, Figure 2) and a 1-kHz tone (Warren, 1970, Figure 3). In both of Warren's investigations reliably more decibels are required to produce numerical judgments of one half of a sound of 100 dB (SPL) than to produce numerical judgments of one half of a sound of moderate intensity, whereas reliably fewer decibels are required to produce numerical judgments of one half of a sound of 35 dB. For the intermediate ranges between 45 and 90 dB, the number of decibels required for half loudness remains approximately constant.

As in the experiment of Figure 8, in both of Warren's (1970, 1973) experiments the local contraction bias affects the judged subjective intensity of the sound. The bias does not affect the number dimension, whether numbers are used as stimuli or as responses.

Avoiding the Contraction Biases

Investigators using ratings may be concerned only with the relative positions of the sensory magnitudes on their rating scale.

If so, they can avoid the contraction bias by using anchors, as indicated at the bottom of the first section of Table 1. At the start of the investigation the greatest stimulus is presented and given the largest rating. The smallest stimulus is presented and given the smallest rating. This encourages the observer to use the complete rating scale for the range of stimuli.

Without anchors, ratings not affected by the contraction bias are obtained only at the neutral point in the middle of a range of named categories. Here the stimulus is not underestimated because it is not judged to be large. It is not overestimated because it is not judged to be small.

In magnitude estimation, the contraction bias can be avoided in theory by using only the judgments of subjectively moderate differences in intensity. The insuperable difficulty is that the observer is not asked to indicate what represents a subjectively moderate difference in intensity, and there is no other way of specifying it using the experimental data.

S. S. Stevens (1971, p. 444) neatly sidesteps this difficulty by following a suggestion he makes 15 years earlier (S. S. Stevens & Poulton, 1956). The contraction biases that occur in magnitude estimation and in magnitude production can be counterbalanced by averaging the results of the numerical judgments and gain adjustments. Since the contraction biases of the two methods are by definition of equal size, they cancel each other because they are in opposite directions.

In judgments of half magnitude, it is not possible to avoid the contraction bias. Warren (1970, 1973) neatly avoids the bias introduced by the observer's tendency to select a response too close to the middle of the range of responses in very first judgments of half loudness. Warren does this by using only the judgments of the variable that receives an average judgment of exactly half the modulus, or number allocated to the standard. This value is neither overestimated nor underestimated. But unfortunately the method can be used only for judgments of half, which is a relatively small ratio. Small ratios tend to be overestimated. Thus Warren's half-loudness judgments give a steep slope on a loglog plot.

The top of the second section of Table 1 indicates that the local contraction bias of Figure 8 for magnitude judgments with small ranges of very high- or low-intensity stimuli can be avoided only by sticking to stimuli of intermediate intensity, as illustrated in the figure. But this still leaves the main contraction bias, which affects all judgments of small stimulus ratios like half and twice loudness.

Stimulus Equalizing Bias

Figure 1B illustrates a model of the stimulus and the response equalizing biases. For the stimulus equalizing bias the two scales at the sides represent stimuli, whereas the scale in the middle represents responses. The observer uses his full range of responses, whatever the size of the range of stimuli. He simply magnifies his response scale to fit a large stimulus range and shrinks his response scale to fit a small stimulus range (Jones & Woskow, 1962). Like the contraction bias, the stimulus equalizing bias affects the observer's very first judgment, because he always has some idea of the range of stimuli to expect.

Stimulus Equalizing Bias in Rating

Harvey and Campbell (1963) compare two ranges of five weights. Columns 2 and 3 of Table 2 show that Weights A and B of 12.7 and 17.9 ounces (362 g and 508 g, respectively) are numbers 1 and 5 at the ends of the narrow range, but occupy the intermediate serial positions 2 and 4 of the wide range.

The two far-right columns of the table give the mean category judgments of separate groups of 40 undergraduates using a 5-point numerical scale. The bottom row shows that the difference between Weights A and B is 2.5 category steps when they are at the ends of the narrow range but only 1.7 category steps when they occupy the intermediate positions in the wide range. Thus the average category rating received by a weight depends partly on the size of the

Table 2
Stimulus Equalizing Bias in Rating Weights

	Weight in ounces		Judgment in ounces		M category judgment using 5-point scale	
Weight	Wide range	Narrow range	Wide range	Narrow range	Wide range	Narrow range
	10.7					
A	12.7	12.7	10.1	11.4	2.4	2.0
		13.9				
	15.1	15.1	14.7	16.4	3.4	3.3
		16.4				
B	17.9	17.9	21.5	22.8	4.1	4.5
	21.2					
B − A	5.8	5.8	11.4	11.4	1.7[a]	2.5[a]

Note. Each column represents results from a separate group of 40 undergraduates (Harvey & Campbell, 1963).
[a] For wide–narrow range, $p < .01$.

range of weights being judged and only partly on its actual weight.

Parducci and Perrett (1971, p. 436) report a similar effect of the size of the range of stimuli. They obtain judgments of the sizes of squares using nine named categories instead of the five numbered categories of Table 2. The average named category given to a particular square changes by 1.5 category steps when the position of the square is changed from the largest in the range to the third largest.

Judgments in Familiar Physical Units

The two middle columns of Table 2 give results from two more separate groups of 40 undergraduates. They show that the stimulus equalizing bias does not affect the judgments of physical weight. The bottom row shows that the difference of 11.4 ounces (323 g) between the judgments of Weights A and B is the same in both ranges. This is because the response scale of physical weight is closely bound to the stimulus scale of physical weight, which students are taught to use at school. Similarly, in Parducci's (1963) results the stimulus equalizing bias affects the numerical category ratings of the number of dots in a rectangle (Parducci, 1963, Figure 22) but not the judgments of the actual number of dots (Parducci, 1963, Figure 12).

In the display in the section entitled Kinds of Responses at the beginning of the article, the response scales are ordered by the closeness of their links to the stimulus scale. First comes a familiar physical measure of the stimulus such as weight in ounces or the actual number of dots. These measures are not affected by the stimulus equalizing bias because the stimuli and responses are closely linked by well-known rules. The remaining kinds of responses in the display, category ratings and magnitude estimates, can all be affected by the stimulus equalizing bias.

Stimulus Equalizing Bias in Direct Magnitude Estimation

The stimulus equalizing bias can have a marked effect in direct magnitude estimation. The observer starts the investigation with what he believes to be a sensible range of responses. He distributes these responses over the range of stimuli presented to him. Thus the observer who is given the smaller stimulus range produces the steeper slope when the data are presented on a loglog plot (Jones & Woskow, 1962).

This is illustrated by the filled points in Figure 6 (results from Montgomery, 1975). The group of 10 psychology undergraduates represented by the filled triangles judge the loudness of the white noise covering a 25-dB range, from a sound pressure level of 70 dB to 95 dB. The separate group represented by the filled circles has a range of 70 dB, almost

three times as large, from a sound pressure level of 30 dB to 100 dB. The ratio of the slopes of the two fitted straight lines is 2:1.

The observer's judgments are not determined entirely by the size of the range of sound levels heard. If they were, the steeper function in Figure 6 would have almost three times the slope of the less steep function, not twice the slope. But the observer's judgments are determined more by the size of the stimulus range than by the differences in loudness.

There are a number of examples of the stimulus equalizing bias in direct magnitude estimation using separate groups of observers for each stimulus range (Poulton, 1968). The bias has a marked effect on dimensions like loudness and brightness, which students are not taught to handle at school. Using a 1-kHz tone, Engen and Levy (1958, Experiment 2) compare a stimulus range extending from 50 dB to 75 dB above threshold, with a range extending from 25 dB to 75 dB. For separate groups of 10 observers, doubling the stimulus range reduces the average slope for loudness on a loglog plot like that of Figure 6 by a ratio of 1.6:1.

Using white noise, Frederiksen (1975, Experiment 2) compares a stimulus range extending from a sound pressure level of 42 dB to 61 dB with a range extending from 42 dB to 80 dB. For separate groups of 10 undergraduates, doubling the stimulus range reduces the slope by a ratio of 1.6:1. In the corresponding Experiment 1 for light intensity, doubling the physical range reduces the slope by a ratio of 1.7:1.

The stimulus equalizing bias has a smaller effect on dimensions such as length and distance, which students are taught to handle at school. In discussing the stimulus equalizing bias within a sensory dimension, Teghtsoonian (1973) gives only three sets of data, all his own. Two are for apparent distance and apparent length, where the stimulus equalizing bias is small as expected.

The third set of data is for the loudness of a 3-kHz tone. Teghtsoonian presents ranges of sound pressure level centered on 84 dB to separate groups of 16 observers. Here doubling the stimulus range from 20 dB to 40 dB has no effect on the slope of the loudness function. It is not clear why this occurs. The instructions state that "the ratios of successive loudnesses might sometimes be very large or very small" (Teghtsoonian & Teghtsoonian, 1978, p. 307). Perhaps this encourages the observers with the large 40-dB range not to underestimate the ratios and so not to be influenced by the stimulus equalizing bias. The effect of transfer from the instructions is discussed in a later section of this review. Whatever the reason, Teghtsoonian (1973, Figure 4) gives the impression that the stimulus equalizing bias has little effect within a sensory dimension. Yet the results just discussed indicate that this is not usually so for loudness or brightness.

Size of the Stimulus Range in Cross-modal Comparisons

In cross-modal comparisons, the inverse relationship between the exponent or slope on a loglog plot and the size of the stimulus range is first pointed out by Jones and Woskow (1966). They use the data from S. S. Stevens (1960, Figure 11 and Table 3), which show the exponents obtained for a number of sensory dimensions, using force of handgrip for the responses. When the exponents are plotted against the reciprocals of the log geometric stimulus ranges, the straight line fitted to the points accounts for 96% of the variance of the points (Teghtsoonian, 1973).

Figure 9 shows the corresponding relationship for 21 of S. S. Stevens's (Note 3, Table 1) investigations using direct numerical magnitude estimation. S. S. Stevens's data are taken from Poulton's summary (1967, Table 1), but with the exponents calculated from the actual subjective and physical ranges used instead of taking S. S. Stevens's best fitting exponents derived from a number of investigations. Also, the physical ranges of sound and vibration are transformed into units of amplitude instead of power by taking the square root, following S. S. Stevens (1966) and Teghtsoonian (1971). S. S. Stevens uses amplitude instead of power because amplitude is more comparable with the measures of length that he uses for other

sensory dimensions. Following S. S. Stevens (1966), in Figure 9 the square root is also taken of the physical range for light, for the dimensions both of brightness and of the lightness of grays. This is because light and sound behave so similarly (J. C. Stevens & Marks, 1965; S. S. Stevens, 1955a). But the fit is slightly better if the range for light is left uncorrected, as Teghtsoonian (1971) does. The figure follows the method of analysis described by Teghtsoonian. The fitted straight line has a slope of 1.43 or log 27. It accounts for 83% of the variance of the points.

Instead of using the exponents of Figure 9, in Figure 10 the average geometric subjective ranges are plotted against the geometric stimulus ranges on a loglog plot. The figure shows that there is little relationship between the sizes of the subjective ranges and the sizes of the stimulus ranges. The tau coefficient of rank correlation is only .28. For 21 points this is not reliable ($.1 > p > .05$).

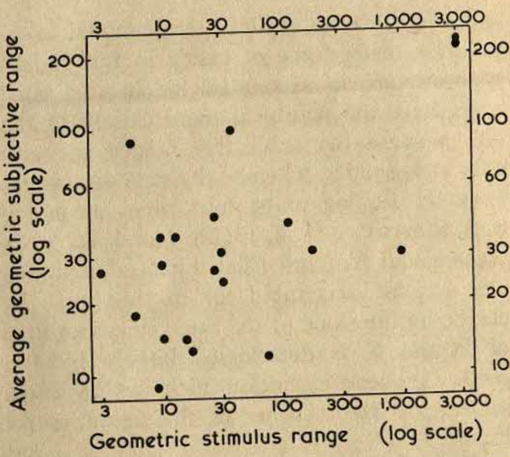

Figure 10. The virtual absence of the stimulus equalizing bias in S. S. Stevens's (Note 3) comparisons between sensory dimensions when exponents are not used.

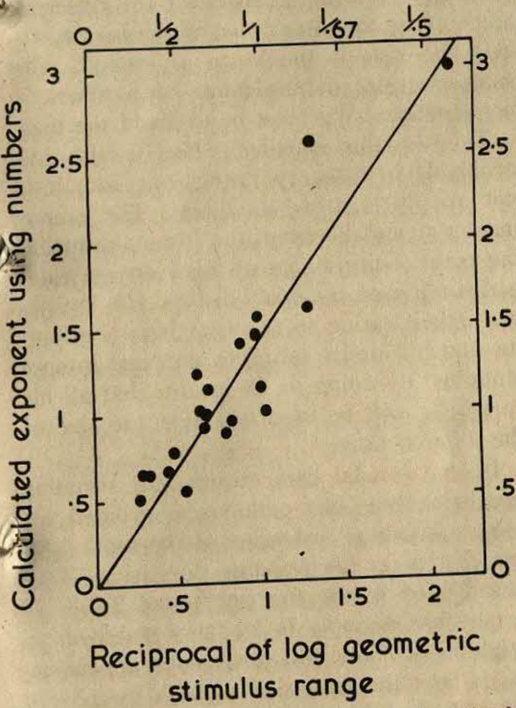

Figure 9. The effect of the size of the stimulus range on the exponents of S. S. Stevens's (Note 3) investigations for different sensory dimensions, using numbers to indicate subjective magnitudes. (The exponents are calculated from the stimulus and response ranges used; they are not precisely the exponents quoted by Stevens. Adapted from Poulton, 1977, Figure 9.)

The overwhelming relationship illustrated in Figure 9 is produced by transforming the subjective ranges into exponents. Figure 10 shows that the subjective ranges run from 9 to 225, a ratio of 25 or 1.4 log units, whereas the stimulus ranges run from 3 to 3,000, a ratio of 1,000 or 3 log units, which is over twice as large in log units. The exponents are the ratios of the log subjective and log stimulus ranges (Teghtsoonian, 1971):

$$\exp = (\log \psi \text{ range})/(\log \phi \text{ range}).$$

Because the subjective ranges vary so much less than the stimulus ranges, they can be approximated by a constant. Using for the constant the slope of the line in Figure 9,

$$\exp = (\log 27)/(\log \phi \text{ range}).$$

The value 27 is the average subjective range of the point for electric shock on the extreme left of Figure 10, which has the smallest stimulus range. In Figure 9 this point stands by itself at the top on the right. Owing to its commanding position it exerts the greatest influence on the slope of the line passing through the origin and fitted to all the points. It insures that the slope will be about log 27.

S. S. Stevens's (1960) cross-modal comparisons using force of handgrip for the responses can be accounted for in the same way. Here the points fit more closely to the line because the subjective ranges vary by only .4 log units, whereas the stimulus ranges vary by 1.6 log units, four times as much. S. S. Stevens's (1966, Figure 2 and Table 1) cross-modal matches using binaural loudness can also be accounted for in this way. In each case the slope of the fitted line, like that of Figure 9, is determined largely by the point for electric shock, which lies by itself in the top right corner of the figure, as in Figure 9.

Clearly Figure 10 is a more appropriate plot for comparing the data from different sensory modalities than a plot like Figure 9. As S. S. Stevens (1971) points out, his stimulus ranges usually extend from not far above threshold to near the maximum that the investigator can obtain or the observer will tolerate. Thus, on both axes of Figure 10 the points are reasonably representative. They show how most of the observer's subjective range on each dimension is related to most of his stimulus range.

Perhaps in the future those interested in comparing sensory magnitudes across modalities will describe the relationships as they are presented in Figure 10. Thus both loudness and brightness have an average subjective range of about 220:1 for a physical amplitude (power$^{\frac{1}{2}}$) range of about 3,000:1. Electric shock has an average subjective range of about 27:1 for a physical-range of about 3:1, whereas cold on the front of the forearm has both an average subjective range and a physical range of about 9:1.

However, Teghtsoonian (1971, 1973) uses the fit of the line like that in Figure 9 and the fits of the corresponding lines with force of handgrip and binaural loudness as the dependent variables, as evidence that S. S. Stevens's subjective ranges are "nearly constant." This conclusion is not compatible with S. S. Stevens's (Note 3) data in Figure 10, nor is it compatible with the comparable data using force of handgrip (S. S. Stevens, 1960) and binaural loudness (S. S. Stevens, 1966). The excellent fits of the lines indicate only that the stimulus ranges are very much larger than the subjective ranges.

Teghtsoonian (1973) also states that variations in the stimulus range have a marked effect in comparisons across modalities but little effect within modalities. This is the wrong way around. The stimulus range has no reliable effect across modalities (Figure 10), unless comparisons are made between exponents. But the stimulus range has a marked effect within modalities that students are not used to handling, such as loudness and brightness.

Avoiding the Stimulus Equalizing Bias

The stimulus equalizing bias can be avoided only by using a range of stimuli of the same subjective size as the range of responses. The filled points in Figure 6 show that the bias cannot be avoided in direct magnitude estimation, because the observer tends to use the same range of numbers whatever the size of the range of stimuli. The subjective size of the range of numbers is not constant, as it must be to avoid the bias.

The stimulus equalizing bias is also unavoidable in category rating, but here it is not usually regarded as a bias. The experimenter may make use of the stimulus equalizing bias to insure that all his response categories are used reasonably often. He anchors his highest rating to the most intense stimulus and his lowest rating to the least intense stimulus. By doing so, he insures that all his categories will be used whatever the size of the stimulus range.

In cross-modal comparisons, the stimulus equalizing bias can perhaps be avoided by using a stimulus dimension of the same subjective size as the response dimension. This is indicated in the first section of Table 1. A possible example is loudness matched to brightness. These two dimensions appear to have about the same sizes of both the physical and the subjective ranges (J. C. Stevens & Marks, 1965; S. S. Stevens, 1955a).

Response Equalizing Bias

Figure 1B illustrates the response equalizing bias as well as the stimulus equalizing

bias. For the response equalizing bias the two scales at the sides represent responses, while the scale in the middle represents stimuli. Whatever range of responses the observer is given, he distributes the responses over the range of stimuli. He uses a larger range of responses when a larger range is available.

Response Equalizing Bias in Rating

The response equalizing bias is not usually regarded as a bias when rating with a small number of categories. In rating sensory magnitudes, the investigator often encourages the response equalizing bias by his instruction. He tells his observer to use the full range of categories that he is given. The instruction insures that the proportional relationships between a set of variables will hardly be affected by the exact number of categories used. This applies to small sets of both named and numbered categories. Thus on a linear plot there is a nearly perfect linear relationship between the average named ratings on a 6-point scale and the average named ratings from separate groups of observers using a 9-point scale (Parducci & Perrett, 1971, Figure 4).

The linear relationship does not hold between a small set of categories and 50 or 100 categories, because the use of both single-digit and two-digit categories introduces the logarithmic bias of Figure 1F.

Response Equalizing Bias in Very First Judgments of Reflectance

In direct magnitude estimation, the response equalizing bias can be demonstrated by giving a standard stimulus a modulus of 10. Separate groups of observers judge the same variable against the same standard, using numbers ranging either between 10 and 0 or between 10 and infinity. Poulton and Simmonds (1963) compare the two response ranges in judgments of the reflectance of gray papers. They use 10 pairs of groups, each group comprising 50 students making their very first magnitude judgments. Of the 10 groups that use numbers ranging between 10 and infinity, 9 have median judgments that differ from the standard by at least 10, whereas none of the 10 groups that judge the same stimuli using numbers ranging between 10 and 0 have median judgments that differ from the standard by as much as 10. To do so, the median would have to be 0. Thus, a larger range of numbers is used when a larger range is available.

Avoiding the Response Equalizing Bias

The response equalizing bias can be avoided in direct magnitude estimation by leaving the observer free to choose his own range of responses. The bias is unavoidable in category rating. As already indicated, in category rating the investigator may encourage the response equalizing bias. It makes his proportional relationships almost independent of the exact number of categories that he uses, provided he sticks to nine categories or less.

In cross-modal matching, the investigator can avoid introducing the response equalizing bias by using a response dimension of the same subjective size as the stimulus dimension. This is indicated in the first section of Table 1.

Bias From Transfer

The biases that result from transfer can be classified by what is transferred:

1. *Transfer from previous stimuli:* Here the present stimulus is judged in the context of previous stimuli. Examples are the centering bias and the stimulus spacing bias of Figures 1A and 1E. These two transfer biases occur gradually as the observer learns the set of stimuli used in the investigation. Another example is the sequential contraction bias, which depends on the immediately preceding stimulus (Jesteadt et al., 1977). These transfer biases have already been discussed. In this section we consider only the remaining transfer biases.

2. *Transfer from previous judgments:* Here it is not just the previous stimuli but also the observer's responses to them that bias his judgments. The present response is made to be consistent with the responses made previously to previous stimuli. Examples of the

influence of one judgment on the next are the transfer between ranges of stimuli, the transfer between ranges of responses, and the transfer from interval to ratio judgments.

3. *Transfer from previous responses:* Here the observer tends to use the same range of responses as he uses in a previous condition with different stimuli.

Transfer Between Ranges of Stimuli

In investigations on transfer between ranges of stimuli, the stimuli to be judged are increased in magnitude or reduced in magnitude. Compared with the judgments of a control group that does not experience the change, after a range of large stimuli, smaller stimuli are judged too small. After a range of small stimuli, larger stimuli are judged too large.

The transfer can be explained as follows: The centering bias of Figure 1A affects the observer's responses to the first range of stimuli. It leaves only the more extreme responses available for the second range of stimuli. The stimuli are therefore judged more extreme than they should be.

Transfer occurs even when the stimuli are judged in familiar physical units such as length in inches, provided the stimulus lines are flashed on a screen for only .2 sec and are therefore not easy to judge accurately (Krantz & Campbell, 1961). Transfer occurs when the stimuli are judged in named categories (DiLollo, 1964; Parducci, 1954, 1956; Ross & DiLollo, 1968a; Tresselt, 1947). Transfer also occurs when a small set of numbered categories is used (Campbell, Lewis, & Hunt, 1958; Melamed & Thurlow, 1971; Parducci, 1963; Pollack, 1964b, Experiment 1), when a potentially large set of numbers is used centered on 100 (Krantz & Campbell, 1961) or extending up to 100 (DiLollo & Kirkham, 1969), and when an infinite set of numbers is used, as in direct numerical magnitude estimation (Melamed & Thurlow, 1971; Ross & DiLollo, 1968b).

Transfer Between Ranges of Responses

The response equalizing bias in very first judgments of reflectance has just been described (Poulton & Simmonds, 1963). Here there is marked transfer from the very first judgments using finite (10 to 0) or infinite (10 to infinity) ranges of numbers to second judgments of the other kind using an infinite range after a finite range or a finite range after an infinite range.

For the very first judgments, 8 out of the 10 comparisons between the finite and the corresponding infinite ranges show that a reliably larger range of numbers is used when the larger range is available. However, on transfer to the second judgment of the opposite kind, 7 of the 8 possible matched comparisons before and after transfer are less marked after transfer ($p < .05$ on a two-tailed Wilcoxon test). Only 3 of the 8 comparisons after transfer still show that a reliably larger range of numbers is used when the larger range is available (Poulton, 1968, Figure 2 and p. 10). Thus after a judgment using the other range of numbers, finite and infinite ranges of numbers give more similar judgments than they do when they are used for very first judgments.

This is presumably because for the very first judgments the students consider only a range of numbers extending from the modulus of 10 either to 0 or to infinity, whereas the second judgments of both kinds are made in the context of a total range of numbers extending from 0 to infinity. The second judgments are therefore more similar than the first judgments.

Transfer From Interval to Ratio Judgments

Fagot, Eskildsen, and Stewart (1966) report reliable transfer from a set of interval judgments made over 3 successive days to a set of ratio judgments made on 3 subsequent successive days (Fagot, Note 4). For the interval or bisection judgments the observer controls the brightness of a circle of light placed between two standard circles of 580 fL and 2 fL, respectively. For the ratio or fractionation judgments, the observer does not see the circle of 2 fL. He adjusts the brightness of the light that he controls to half the brightness of the light of 580 fL.

When the ratio judgments are performed first, the average geometric mean for half

brightness is 52 fL, giving a mean slope on a loglog plot of .28. When the ratio judgments are performed after the interval judgments, half brightness falls reliably to 13 fL, giving a mean slope of only .18. The ratio of the two slopes is 1.6:1. The interval bisection judgments are not appreciably affected by prior ratio judgments. The average geometric mean falls only from 47 to 41 fL. This could be due to initial differences between the two groups of four observers who perform the two conditions in opposite orders.

The reliable transfer can be explained quite simply in terms of the hypothetical zero used for the ratio judgments. Suppose an observer first gives an average bisection judgment of 47 fL between the standards of 580 and 2 fL. When the standard of 2 fL is removed for the ratio judgments, the observer realizes that he has now to judge a larger range of brightnesses, extending from 580 fL to 0 fL. He therefore selects a half brightness less than his previous average of 47 fL.

In contrast, the observer who starts by making the ratio judgments has to get on as best he can without having seen a specified lower bound to the range of brightnesses. When he is subsequently presented with a lower bound for his bisection judgments, he of course uses it.

Transfer From the Range of Numbers Used in the Instructions

In direct magnitude estimation, the numerical examples used by the investigator in explaining the technique can reliably affect the slope of the psychophysical function that he obtains. In a series of investigations, G. H. Robinson (1976) gives alternate observers different numerical examples. The standard stimulus is always called 100. For half the observers the written instructions state that if the variable is one and a half times the standard, it should be called 150. If the variable is half the standard, it should be called 50. For the other half of the observers the instructions state that if the variable is seven and a half times the standard it should be called 750. If the variable is one quarter of the standard, it should be called 25. The range of numbers specified is simply increased from 50–150 to 25–750, an increase in ratio from 1:3 to 1:30.

In G. H. Robinson's (1976) Experiment 1 for magnitude estimations of auditory pulse rate, the increase in the specified range of numbers increases the exponent from .87 to 1.3 and from .89 to 1.3 in a replication, ratios of about 1:1.5. In Experiment 2 for the loudness of a 1-kHz square wave, the exponent increases from .73 to 1.0 and from .77 to .95 in a replication, ratios of about 1:1.3. All four increases are reliable. The plotted functions are concave downward like those at the top of Figure 3B. Each function for the larger range of numbers is a little steeper than the function for the smaller range. For the smaller range of numbers, each function is a good deal more concave downward at the upper end than the functions at the top of Figure 3B, as if the observers run out of high numbers.

Clearly, the method of direct magnitude estimation is extremely sensitive to numerical examples given in the instructions. If an investigator wishes to obtain unbiased data, he should not use numerical examples. Unfortunately S. S. Stevens (1971, p. 428) recommends their use, suggesting numbers 20 times and one fifth of the standard, a ratio of 1:100. Only 4 of Stevens's 21 average geometric subjective ranges, illustrated in Figure 10, are as large or larger than this. So if he does use these instructions, in most of his investigations he is biasing his observers into giving unduly large exponents. This may explain why other investigators often find rather smaller exponents than S. S. Stevens does.

The disturbing feature is that the investigators who now follow Stevens in giving numerical examples may suggest ranges of numbers to their observers that will produce the sizes of exponents they expect to find. Investigators would be foolish to suggest ranges of numbers that produce unexpected sizes of exponents. Yet suggesting appropriate ranges of numbers will produce a spurious consistency between the exponents and the theory. Unfortunately investigators do not often report the exact instructions that

they give. In these cases the reader has no idea whether the investigator finds the size of exponent that he does find simply because he suggests the particular range of numbers to his observers.

Transfer From the Range of Numbers Used in a Previous Investigation

S. S. Stevens and his colleagues use the same members of the departmental staff and graduate students for more than one investigation (S. S. Stevens, 1959). From the evidence just reviewed on the transfer of ranges of numbers, it is almost certain that there is transfer of the range of numbers from one investigation to the next. This is a bias that S. S. Stevens and his students ignore.

S. S. Stevens (1971, p. 428) even recommends "under some circumstances," which he does not specify, clarifying the nature of the task before starting an investigation. This is done by getting the observer to match numbers "to an easier continuum, such as apparent length of lines, or apparent size of circles" (Stevens, 1971, p. 428). Yet as is pointed out in an earlier review (Poulton, 1968),

> It would be too easy for the experimenter to select a range of lengths of lines calculated to elicit the set of numbers which he believed to be appropriate to the range of stimuli which he was subsequently going to present to the observer. Clearly, the experimenter would be foolish to present lines which elicit a quite inappropriate set of numbers, in view of the expected transfer effects. The experimenter is thus in a predicament which is better avoided. (p. 4)

Avoiding Bias From Transfer

As the third section of Table 1 indicates, the only way of avoiding bias from prior conditions is to use separate groups of observers for each condition. Bias from instructions and demonstrations can be avoided by using unbiased instructions and no demonstrations. Transfer from previous stimuli, judgments, and responses can be avoided only by restricting each group of observers to a single judgment.

The difficulty with using separate groups is the large individual differences in judging sensory magnitudes. S. S. Stevens (1971, Figure 3) reports that his individual exponents for loudness range from .4 to 1.1, a ratio of 1:2.7. To obtain a reasonably precise average numerical value, it is therefore necessary to use large numbers of observers. Yet S. S. Stevens and his colleagues typically use only 10 or 12 observers in each investigation. To obtain data that are comparable across investigations, they need to stick to the same observers or to use groups of observers who are known to give comparable magnitude judgments because they have served in previous investigations. Yet the use of selected trained observers almost certainly introduces bias from transfer.

Avoiding all Biases

The fourth section of Table 1 indicates how to avoid all the biases that can be avoided. As already pointed out, in category rating it is not possible to avoid the stimulus and response equalizing biases. An investigator who wishes to avoid these two biases does not use ratings.

In magnitude estimation the response equalizing bias can be avoided by leaving the observer free to choose his own range of responses. However, the only way of avoiding the stimulus equalizing bias is by the cross-modal matching of sensory dimensions with subjectively equal-sized ranges, as indicated at the bottom of Table 1 on the right. This matches only subjective magnitudes in one sensory dimension to subjective magnitudes in another sensory dimension with a subjectively equal-sized range. There is no sure unbiased method of matching subjective magnitudes to numbers, because the observer tends to use the same range of numbers whatever the size of the range of stimuli. Thus the subjective size of the range of numbers varies with the size of the range of stimuli.

Clearly, avoiding all possible biases provides so little useful data for so much effort that not many investigators are likely to contemplate it. The most practical alternative is to collect data with the minimum of known biases by balancing the biases against each other, as suggested by S. S. Stevens (1971, pp. 444–446). Then make checks using

separate groups of untrained observers to estimate the sizes of the residual biases. Finally, the data should be corrected for the residual biases.

A difficulty with this alternative is that the effects of the residual biases may be considerably larger than the effects that the investigator wishes to study. Also, the biases may interact with the effects being studied. Unfortunately, at the present time most investigators simply collect biased data without attempting to correct for the biases or even to measure and report them.

Behavioral Treatment of Children's Fears: A Review

Anthony M. Graziano, Ina Sue DeGiovanni, and Kathleen A. Garcia
State University of New York at Buffalo

Behavioral literature on childhood fears, including conceptual models, normative research, and fear-reduction studies is reviewed. The main conclusions are as follows: (a) The information value of nearly 60 years of normative studies is meager, and their continuation is of doubtful value; (b) most research has been limited to laboratory studies of mildly to moderately fearful children, and few data exist on severe fears studied in the child's natural environment or on the clinical prevalence of fear; (c) cognitive and developmental factors have been largely ignored; (d) modeling is the most frequently used and reliably effective fear-reduction strategy; (e) a cognitive, verbal–mediation approach is promising, but is not yet sufficiently researched; (f) there is little evidence that systematic desensitization or contingency management strategies are effective. Implications for large-scale fear reduction and prevention are discussed. The need for research that recognizes the complex paradigms of children's fears is suggested.

This article is a selective review of behavioral treatment of children's fears, an area relatively neglected by behavior therapists and researchers despite their considerable attention to adult fear reduction (Graziano, 1975). Adults seem to minimize the importance of children's fears, viewing them as common and transitory and thus not a particularly serious part of normal development. But children's fears may not always be transient, and some, such as specific animal phobias (Jersild, 1968; Jersild & Holmes, 1935a; Marks & Gelder, 1966) and fear of physical injury or psychic stress (L. C. Miller, Barrett, Hampe, & Noble, 1972b) may persist as adult problems. Children do experience fears, often intense and disturbing, and the psychological suffering of a fearful child, even if it remits in a few years, is at least as worthy of professional concern as is the suffering of adults. There seems good reason for urging more study of fear reduction in children.

Because of this review's behavioral focus, the large psychoanalytic literature is not included. Likewise, school phobia articles, which outnumber those of any other fears by about 25:1 (L. C. Miller, Barrett, & Hampe, 1974), have been well reviewed elsewhere (Gelfand, 1978; Hersen, 1971; Kelly, 1973) and are only briefly discussed.

The modern psychological study of children's fears is nearly 60 years old. The literature consists of psychoanalytic and behavioral case studies, normative fear surveys, controlled fear-reduction experiments that are mainly clinical analogs, and a few theoretical articles and reviews. Much of the literature is psychoanalytic, but interestingly, the earlier (e.g., Jones, 1924a, 1924b; Watson & Rayner, 1920) and the most recent articles have been behavioral.

Berecz (1968) concluded that the research has been "disappointing," giving "only hints" of the nature and incidence of childhood fears. A decade later, the situation regarding normative research appears much the same. A recent increase in behavioral studies of child fear reduction includes some well-designed research (e.g., Bandura & Menlove, 1968; Kanfer, Karoly, & Newman, 1975; Kornhaber & Schroeder, 1975; Melamed & Siegel, 1975; Murphy & Bootzin, 1973). Overall, however, the bulk of research still

Requests for reprints should be sent to Anthony M. Graziano, Department of Psychology, State University of New York, 4230 Ridge Lea Road, Buffalo, New York 14226.

leaves us with hard-to-interpret data, results that are more suggestive than definitive, and an important area that is very much in need of more empirical research.

One reason for the persistence of uncertain results may be a generally held assumption that knowledge about adult fears is sufficient for understanding fears of children, an assumption that may have encouraged inappropriate concepts and approaches. Piaget's work (e.g., 1929, 1951) on cognitive development should alert one to the dangers of considering children to be miniature adults. Berecz (1968) suggested other reasons, namely, a too inclusive use of the term *phobia* to describe "such a variety of conditions" as to make the term meaningless and definitions of phobias that are heavily biased by theoretical conceptions.

Ethical restraints, too, make this a difficult area in which to conduct research. For obvious ethical reasons children cannot be subjected to controlled presentations of fear stimuli in order to measure their reactions. Less intrusive measures, such as self-reports, questionnaires and observations taken in clinical treatment and research, must be used. To these constraints add the problems of obtaining reliable and valid personal information from children, and some of the difficulties become apparent. Accordingly, researchers have tended to tread lightly, using nonintrusive methods that rely heavily on retrospective, subjective reports based on unsystematic self-observations. Vitually all of the normative data were drawn from one form or another of retrospective, subjective report. Frequently the data were from second-person (parents and teachers) verbal reports or were limited to observations made in clinical case studies. These limitations may largely account for the lack of hard data that still characterizes the field despite more than a half century of psychological study.

Definitions: Fears, Phobias, and Clinical Problems

Despite these vagaries, there is fairly good general agreement on definitions of *fear* and *phobia*. Fear is commonly thought of as a normal reaction to genuine threat that involves at least three response systems: (a) overt behavioral expressions, (b) covert, subjective feelings and thoughts, and (c) physiological activity. The term *phobia* is commonly used to denote a specific fear in which at least one of the three elements is excessive, persistent, and unadaptive (Marks, 1969; L. C. Miller et al., 1974). Thus it is generally agreed that fear is a normal response to threatening stimuli, whereas phobia is an unreasonable response, often to usually benign or ill-defined stimuli.

Severity ranges from the mildly fearful responses of many children toward darkness, dogs, and so on to disabling, highly intense levels of fear. It is reasonable to assume that fears presented at clinics for professional intervention are the most severe fears. Two questions are raised immediately when one considers *clinical* fears. First, how are clinical fears to be defined other than by virtue of the fact that clients show up in clinics for treatment? Hampe, Noble, Miller, and Barrett (1973) found that most children, even those with intense fears, overcome them with or without treatment within 2 years. But some do not, and they might appropriately be classed as having fears of *clinical* duration. Intensity and duration might be important defining characteristics, and we suggest that clinical fears be defined as those with a duration of over 2 years or an intensity that is debilitating to the client's routine life-style. The second question is, how prevalent are severe fears and should current research be focused only on severe fears or on both mild and clinical levels of the problem? As is shown in the review of controlled studies, most researchers treat all levels of severity the same, working primarily with mildly fearful children and generalizing to all phobic children. A recent review of behavioral treatment of clinical phobias by Mathews (1978) emphasizes the inappropriateness of generalizing from what are essentially analog studies to treatment of clinical fears. This limitation seems to have occurred because both mild and severe levels of fear are important research areas, and mildly fearful children are considerably easier to recruit as research subjects than are severely fearful children. However, it seems important to identify clearly

the severity of subjects' fears and the limitations that severity places on generalization of the data, especially since one does not know whether mild and clinical fears operate according to identical principles.

We know surprisingly little about childhood fears of high intensity, long duration, and disturbing content. L. C. Miller et al. (1974) estimated that school phobics make up 1% of the school-age population, whereas other child phobics may "run as high as 20 per cent" (p. 91). In his review, Marks (1969) found little data on the frequency with which phobic children are referred for psychiatric treatment. Graham (cited in Marks, 1969) reported five cases of school refusal out of 162 clinical referrals and only 10 specific phobias in 239 cases referred to a children's psychiatric hospital. Rutter, Tizard, and Whitmore (1970) screened all 10- and 11-year-old children ($N = 2{,}199$) on the Isle of Wight and found only 16 children to have clinically significant and handicapping phobias. Their screening procedure omitted those with monosymptomatic phobias, and thus 16 is a conservative estimate. In the most recent attempt to assess clinical prevalence, Graziano and DeGiovanni (1979) obtained questionnaire data from 19 behavior therapists. They reported a total of 547 children referred within the previous 6 months, of which 37, or 6.8%, were referred for treatment of clinical level fears, as defined above. At present only guesses can be made about the nature and extent of the clinical problem of children's fears.

Fear Paradigms

Although several theoretical models have been advanced, none adequately explains the etiology and maintenance of phobias. The major conceptual models are psychoanalytic and behavioral, with ethological theory and a cognitive–developmental model representing less common but potentially important approaches. The major focus of this article is on the behavioral literature.

Behavioral approaches consist of three paradigms, each of which assumes that fears and phobias are learned: respondent conditioning, operant conditioning, and the two-factor theory of learning. The respondent model postulates that anxiety is the central aspect of phobic behavior and that any neutral stimulus present at the time a fear response occurs may become a conditioned stimulus. In future presentations it will elicit the associated fear response. The conditioning occurs if the original conditioning situation was of high intensity or was repeated a number of times. The conditioned fear is presumably maintained in the absence of reinforcement because the avoidance behavior precludes the requirements for extinction, that is, the repeated confrontation of the actually benign conditioned stimulus without its pairing with the unconditioned stimulus. A decrease in avoidance behavior can be achieved by replacing the conditioned anxiety response with a response antagonistic to anxiety (e.g., relaxation) that inhibits or weakens the anxiety. Wolpe's (1974) systematic desensitization is best known of the therapy procedures based on this *reciprocal inhibition* paradigm. The major problems with the respondent model are that it does not explain why some neutral stimuli seem more likely than others to become conditioned fear stimuli, and, although it attempts to, it does not adequately explain the maintenance of phobic behavior in the absence of reinforcement.

Operant models hold that reinforcement, rather than anxiety, primarily social reinforcement such as parental attention, is the central aspect of phobic behavior. Children are presumably taught to be afraid by parents and other significant persons who selectively, albeit unintentionally, attend to and reward fearful behavior. Therapy procedures based on operant models attempt to reduce children's phobic behavior by changing the reward structure in their immediate environments, that is, by teaching parents to ignore phobic behavior and to differentially reward alternative nonfearful approach behaviors. The major problem with the operant paradigm is its failure to adequately account for and therapeutically treat the subjective feelings of intense fear or anxiety and their accompanying thoughts that are often experienced by phobic children.

Modeling, one of the most frequent and promising therapeutic techniques, is based on social learning theory, which is an extension of operant conditioning. Modeling assumes

that behavior can be changed through the vicarious experience of rewards (either tangible or cognitive) for new behavior or of the informational value of the modeled behavior. For example, a child's phobic avoidance of dogs may be decreased by his or her vicarious experience of the rewards given to another child (the model) who approaches a dog. Effective rewards can be either objective, such as verbal praise explicitly given to the model for approach behavior, or subjective and nonobservable, such as internal cognitions of social praise generated within the observing child (e.g., "That child is brave for approaching that dog. I will be brave for approaching that dog.") Although both tangible and cognitive stimuli may be equally effective in generating the initial performance of new approach behaviors, it seems likely that reinforcing cognitive self-statements (either those generated by the child spontaneously or those supplied by the therapist) are crucial in maintaining the new approach behavior. Similarly, the acquisition, as well as the therapeutic extinction, of phobic behavior may involve cognitive self-reinforcers, such as "She or he got knocked down by playing with that dog; I will get hurt if I play with that dog." Although the therapeutic effects of modeling with phobic children have been explored (e.g., Bandura, Grusec, & Menlove, 1967), little attention has been given to examining directly the nature and function of cognitive variables in the acquisition, maintenance, and extinction of children's phobias. In light of the role that such cognitions seem to play in phobic behavior, this is a major lack of the current research.

The two-factor theory incorporates both respondent and operant learning concepts. First proposed by Mowrer (1939), it postulates that phobias originate according to the respondent conditioning paradigm and are maintained according to the operant conditioning model. After initial respondent conditioning of fear or anxiety with the conditioned stimulus, anxiety reduction associated with avoidance of the noxious stimulus becomes a positive reward or reinforcer, since anxiety or fear is unpleasant. Thus, anxiety reduction becomes the reinforcement for avoiding the noxious stimulus created by respondent conditioning. Problems with the two-factor theory have been extensively discussed over the last several years (Bandura, 1969; Herrnstein, 1969; Rachman, 1976, 1977, 1978). In brief, (a) the theory assumes that phobias are mediated through the autonomic nervous system, although studies by Solomon and Turner (1962) and Bandura (1969) suggest that behavior is regulated in large part by the central nervous system; (b) it does not explain why people fail to acquire fears in what are theoretically fear-evoking situations (e.g., air raids); (c) it fails to explain the "choice of symptom" issue of why some stimuli are more likely than others to become fear signals, that is, the distribution of human fears is not consistent with the equipotentiality premise of the theory; (d) it accepts the faulty assumption that all fears are acquired directly through classical conditioning, although it has been shown that operant conditioning and observational learning can also indirectly produce fearful behavior; (e) it fails to explain why active avoidance behavior is so persistent and does not extinguish in the absence of further reconditioning or trauma experiences to maintain the anxiety associated with the conditioned fear stimulus. In response to some of these problems, Herrnstein (1969) has reported recent experiments showing that the conditioned stimulus may function as a *discriminative* stimulus for the avoidance response rather than as a noxious stimulus whose removal is inherently reinforcing, as two-factor theory requires.

Rejection of the two-factor theory has significant implications for both treating and measuring phobias, in that it suggests the three major components of fear (avoidance behavior, subjective experience, and physiological disturbance) can covary, vary inversely, or vary independently (Rachman & Hodgson, 1974). Routine tests of these three components should be carried out as a pretreatment measure to determine the amount of synchrony/desynchrony among the three elements and to determine which element(s) does (and does not) require direct treatment. Different treatments may tap different elements of a phobia more or less efficiently. Refutation of the two-factor theory also raises the important question of whether one needs

to treat each element directly or whether one can assure patients that if one cures one component (e.g., avoidance behavior), the others will follow automatically (e.g., subjective experience). Thus, although the two-factor theory itself does not yield any new treatment techniques, the theoretical and empirical debates over the theory have caused researchers to question both the necessity for and the sequencing of various therapy components based on respondent and operant paradigms.

The major theoretical models reviewed briefly here are not adequate to explain childhood phobias. Two issues that appear to us to be of major importance are not even addressed by the existing models. These issues are (a) the role of cognitions in the origin, maintenance, and reduction of fears and (b) the influence of developmental issues in childhood phobias. The idea that cognitions may influence phobic behavior is one that is gaining attention both on a theoretical level (Rachman, 1977) and on a treatment-oriented level aimed at fear reduction (e.g., Kanfer et al., 1975; Kissel, 1972; Meichenbaum & Turk, 1976). Developmental issues have long been ignored in this area, although recently some theorists (e.g., Bowlby, 1973; Kissel, 1972; L. C. Miller et al., 1974) have suggested that these issues may be important. Both cognitive and developmental issues deserve further exploration, which might lead to a more complete theoretical model of childhood fears and phobias.

There are two major categories of research in children's fears: normative fear survey research and fear-reduction studies.

Normative Fear Survey Research

It seems reasonable to expect that knowledge about the normal fears of children is important in understanding their pathological fears. At least 22 papers since 1932 have reported normative data, but they reveal little clear information. One point, however, is clear: The normative research has focused almost exclusively on the identification of fear stimuli by asking the question "What do children fear?" and then attempting to relate the number, type (content), or intensity of the fear stimuli to demographic parameters such as age, sex, and socioeconomic class and to other, presumably pathological, behavior. Most of the studies have focused on the number of fears, and some have focused on the content or type of fear, but very few have dealt with the intensity of fear. Despite many methodological problems, to be summarized later, some consistencies do emerge.

Sex Differences

One of the most consistent findings is that however fear is measured, girls obtain higher fear scores than boys (Angelino, Dollins, & Mech, 1956; Bamber, 1974; Croake, 1969; Croake & Knox, 1973; Cummings, 1944; Lapouse & Monk, 1959; Pratt, 1945; Russell, 1967; Scherer & Nakamura, 1968; Spiegler & Liebert, 1970). Although no study reported generally higher fears for boys, three articles (Maurer, 1965; L. C. Miller, Barrett, Hampe, & Noble, 1971; Nalven, 1970) found no sex differences.

Though the number of reported fears in relation to sex has been studied, there are uncertain data on the relationship between sex and either the content or the intensity of fears. Lapouse and Monk (1959) found significant sex differences in fear content, specifically in the percentage of children who feared certain objects. Pratt (1945), however, found no sex differences in fear content. MacFarlane, Allen, and Honzik (1954) collected data on fear intensity, but did not report any analysis. Other studies (Bamber, 1974; Russell, 1967; Scherer & Nakamura, 1968) found that girls report a greater fear intensity than boys. Although sex differences in content and intensity are still uncertain, the finding that girls report a greater number of fears appears frequently enough and with no conflicting evidence of reverse findings to be accepted as a reliable finding. Interpreting the finding, however, is difficult. One cannot tell from these data if the girls' higher scores reflect greater fear reactivity or if other factors, such as sex role expectations, operated. Consistent with a general role model of feminine behavior, girls may be more willing than boys to admit their fears. Similarly, in those studies using parents' reports, the adults may

incorrectly, but nevertheless reliably, attribute greater fear to girls than to boys. Grossberg and Wilson (1965) and Wilson (1967) suggested the operation of sex role factors in adult fear scores, whereas Scherer and Nakamura (1968) and Bamber (1974) suggested that similar sex role factors might account for the data on children and adolescents. One would expect, too, that if sex role stereotypes and behavior are changing, future fear surveys might find smaller and less reliable sex differences. In this regard it is interesting that the studies reporting no differences are fairly recent (from 1965 on), which possibly reflects some contemporary changes in sex stereotyping.

Age

Overall, there appears to be a general decrease from young childhood to late adolescence in the percentage of children who report one or more specific fears (Cummings, 1944, 1946; MacFarlane et al., 1954) and in the simple number of fears reported (Angelino & Shedd, 1953; MacFarlane et al., 1954; Nalven, 1970; Scherer & Nakamura, 1968). However, the decrease may not be in simple linear relationship with age, as several studies have shown a sharp increase in the number of reported fears around ages 9–11 (Angelino & Shedd, 1953; MacFarlane et al., 1954) or a peak at age 11 (Chazan, 1962; Morgan, 1959). On the other hand, several studies have reported no significant relationships of fear with age (Croake, 1969; Croake & Knox, 1973; Lapouse & Monk, 1959; Maurer, 1965; Russell, 1967).

Some studies suggest that the *type* of fear reported is related to age (Angelino & Shedd, 1953; Nalven, 1970; Scherer & Nakamura, 1968). Jersild and Holmes (1935a) observed that in infancy children's fears arise in response to occurrences in the immediate environment (e.g., loud noises, loss of support, etc.). As a child grows older, his or her range of fears grows wider and he or she acquires the ability to dwell on the past and to anticipate the future. Thus many of his or her fears will change to those of an anticipatory nature. This observation seems generally borne out by the data, as reviewed by Scherer and Nakamura (1968). The most consistent findings are an age-related decline in fear of animals (Angelino et al., 1956; Bauer, 1976; Lapouse & Monk, 1959; Maurer, 1965; Shepherd, Oppenheim, & Mitchell, 1972) and in fears of the dark or of imaginary creatures (Bauer, 1976; Holmes, 1936; Maurer, 1965; Shepherd et al., 1972) and an age-related increase in school and social fears (Angelino et al., 1956; Lapouse & Monk, 1959).

L. C. Miller et al. (1972b), in contrast with most other studies that showed an age-related decline in animal fears, reported that fear of small animals, along with "moral" fears, "emerges more clearly in adult life" (p. 268). L. C. Miller et al. extracted three factors as the "principle dimensions" of children's fear: (a) fear of physical injury, (b) fear of natural and supernatural dangers, and (c) fear of psychic stress (e.g., social events, examinations, etc.). The second factor was found to diminish with age, whereas the other two factors reportedly "emerge early and continue through much of the life span" (L. C. Miller et al., 1972b, p. 268). Similar factors have been reported by other investigators (Russell, 1967; Scherer & Nakamura, 1968).

An important developmental question concerns the relationship between age and degree or intensity of fear. Do children of different ages react differently to the same type and intensity of fear stimuli? It is commonly believed that young children have more intense or all-encompassing fear reactions than do older children. But to date there has been little investigation of this question.

Although detailed information on the relationship of age and the number, kind, intensity, and factor structure of children's fears is not known, there is consensus that age is an important variable in fear reactions.

In summary, as children grow older, their fear patterns change, but not in simple linear relation with age. Some fear stimuli remain operative, others lose their value, and some new ones emerge. These tentative conclusions about fear and age are drawn from a mass of research data. They appear reasonable but hardly surprising, and they seem a rather small output for so much research activity.

Socioeconomic Class

As with age, socioeconomic class (SEC) appears to be an important variable in children's fears, but the details of the relationships are not clear. Several studies have reported SEC differences in the type (content) or number of reported fears (Angelino et al., 1956; Bamber, 1974; Jersild & Holmes, 1935a; Nalven, 1970; Newstatter, 1938). The more reliable of the two findings is the variation found in content, with lower SEC children reporting more fears of specific events or others such as violence, whippings, dope peddlers, switchblades, drunks, money, rats, and cockroaches (Angelino et al., 1956; Nalven, 1970). In comparison, higher SEC children feared heights, car accidents, train wrecks, and large categories such as poisonous insects or dangerous animals. The fears of the lower SEC children ("ghetto" children in Nalven's, 1970, study) strongly suggest the socially determined nature of fear content and an immediacy and reality basis for the expressed fears of the lower SEC children. The data suggest that these children may perceive their immediate environments as far more hostile than do the higher SEC children. This is a hypothesis well worth testing, but it has not been investigated within the scope of the fear literature.

Although it seems clear that fear content varies with SEC, it is not clear whether the number of reported fears also varies. Some studies (Angelino et al., 1956; Bamber, 1974; Croake, 1969; Croake & Knox, 1973; Jersild, Markey, & Jersild, 1933) have found a greater number of fears for lower than for higher SEC children. However, as Garcia (Note 1) pointed out, Angelino et al. (1956), a frequently cited study, seemed to misinterpret their own data. The authors concluded that both content and number of fears varied with SEC, but their own data supported only the difference in content. Further, Nalven (1970) made an observation that may have bearing on this issue, namely, that lower SEC children compared with the others tended to list specific fear items rather than more generic groupings. For example, they listed specific animal fears (rats and cockroaches), whereas higher SEC children noted groupings such as dangerous animals or poisonous insects. If this difference in the level of abstraction of the concepts used by different SEC children was reliable, it may have generated a spurious finding of different numbers of fears between the groups. As Garcia suggested, studies that instruct children to simply list their fears are probably most susceptible to such an artifact. Finally, no studies have reported data on SEC differences in the intensity of fears.

Fears and Pathological Behavior

It seems a reasonable prediction that children's fears are positively related to other behaviors that are usually considered to be pathological. However, except for the suggestions of such a relationship found in clinical case studies, there seems to be little data to support this prediction. Some of the case studies (e.g., Tasto, 1969) have even pointed out that the child's severe fear was a specific and isolated reaction, apparently not related to other behaviors. Some studies, however, have shown a relationship between fear and manifest anxiety (Scherer & Nakamura, 1968) and between fear and neuroticism (Bamber, 1974). MacFarlane et al. (1954) reported that children's fears were related to a variety of problems such as general anxiety, irritability, and timidity, all depending on age and sex. Their correlations, however, were low and were not consistent across ages. Hampe et al. (1973) reported a general response to treatment over a 2-year follow-up period. As the primary fear reduced in time, so did "a host of other deviant behavior" (p. 451). These authors suggested that not only are fears related to other pathological behavior, but fears are related to other pathological behavior in some causative or mutually sustaining manner.

On the other hand, L. C. Miller et al. (1971) found no correlation between school phobia and other pathological behaviors, and Lapouse and Monk (1959), using detailed individual interviews with a random sample of the parents of 482 children, found no significant correlations between fears and pathological behaviors such as bed-wetting, nightmares, nail-biting, frequent temper losses, and so on. Lapouse and Monk also interviewed a sizable subsample of children

to compare their reports with the parents' reports and, again, found no significant relationships between fear and pathological behavior.

Thus there appears to be weak evidence that children's fears may be related to general conditions such as anxiety, but there is no clear support for the relation of fear with specific pathological behavior such as bed-wetting or tantrums. A reasonable hypothesis, not yet explored, is that the intensity rather than the simple number of fears may be positively related to behavior pathology. At this point, however, there is little evidence that childhood fears are related to other pathological behaviors.

Methodological Problems in the Normative Studies

For the most part methodologies have been fairly straightforward and simple, involving variations of questionnaire and interview methods that range from the earlier studies in which subjects were asked to list their fears to the more recent use of factor-analyzed rating scales. Only Jersild and Holmes (1935a) attempted to obtain normative data by direct observation methods.

In the earlier studies, children or parents were requested to "write down" or "tell me the things you are afraid of" (e.g., Maurer, 1965; Pratt, 1945) or to "list the fears of other children in your own age group" (e.g., Angelino et al., 1956; Nalven, 1970). Many studies using this list or list-and-rank method asked the children directly (Angelino et al., 1956; Croake, 1969; Maurer, 1965; Nalven, 1970; Pratt, 1945). Others, however, who sought greater reliability or perhaps more ease in obtaining data used mothers as informants (e.g., Hagman, 1932; Lapouse & Monk, 1959). Only Lapouse and Monk reported any measure of concurrent validity. They interviewed an additional sample of 193 children and their mothers separately, using different interviewers. Comparing those independent interviews, they found that the largest discrepancy concerned the mothers' and children's assessment of the number of children's fears and worries, with "the mothers, in comparison with the children, underestimating by 41 per cent" (Lapouse & Monk, 1959, p. 812). Their results cast doubt on the validity of mothers' or children's self-reports in this and other studies. Marks and Gelder (1966) asked adults to recall the childhood onset of their fears; Abe (1972), in a study carried out in Japan, compared self-report fears of 242 mothers with their childhood fears as recalled and reported by *their* mothers.

Of all the list-and-rank procedures, those of Lapouse and Monk (1959) appear to have been the most carefully executed. Using the Buffalo city directory, they drew a random urban sample and employed trained interviewers to conduct hour-and-a-half interviews with the mothers of 482 6–12-year-old children. The interviewers obtained data on the number and kinds of fears, on sex, age, race, and economic status, and on the occurrence of other behaviors such as bed-wetting, nightmares, and a variety of "tension phenomena" such as nail-biting. As mentioned, an additional sample of children and their mothers were also carefully interviewed to compare the children's and mothers' responses.

The list-and-rank approach is characteristic of the studies through 1966. The studies did identify fear stimuli, but they share a number of weaknesses. Two of the shortcomings specific to this approach are that one cannot be certain that the lists of fear stimuli are complete, and although data are generated on the number and kinds of fear stimuli, they tell us nothing about the degree of fear-stimulating power of each item or the intensity of the children's fear reactions.

Since 1967 some of the normative studies have been more sophisticated, but still have focused on the essential question, "*What* do children fear?" These later studies used rating scales that provided data not only on the number and types of fear stimuli but also on the relative degree of fear reactions to the different stimuli. In these studies, too, factor analyses were used to identify the presumed factor structure of children's fears.

The major approach in the rating scale studies is to instruct the child (Bamber, 1974; Russell, 1967; Scherer & Nakamura, 1968) or the parents (L. C. Miller, 1967; L. C. Miller et al., 1971; L. C. Miller et al.,

1972b) to rate each of the listed fear stimuli for intensity of reaction. The results are then factor analyzed, usually with added demographic or other behavioral measures.

Although fear-survey rating scales provide more information than the earlier approaches and have an advantage of standardization, their reliability and validity are still equivocal (Geer, 1965; Lang & Lazovik, 1963; Manosevitz & Lanyon, 1965). For example, L. C. Miller et al. (1971, 1972b) reported no validity data and only split-half reliability on the Louisville fear survey, perhaps the most often used fear rating scale for children. Although the split-half reliability was acceptable ($r = .80$), no data were reported on test–retest reliability or on any form of validity. Split-half reliability and factor analyses, the most commonly reported measures on fear rating scales, are measures of only the internal consistency of the scales. Additional data need to be collected on the stability (test–retest) and validity of fear rating scales before any but tentative conclusions can be drawn.

Taken together, the normative studies involve so many procedural differences and methodological problems that clear comparisons and reliable conclusions are difficult to draw. In addition to the difficulties specific to each method already pointed out, the field as a whole suffers from a number of generally shared problems. One major limitation is that the data are essentially subjective, that is, they are usually second-person reports by parents and sometimes first-person reports by children. Further, the adult second-person reports are usually limited to mothers of the children, with whatever sex role biases and attributions may be operative. We do not know, for example, if fathers' reports would generate different results. Perhaps it might be hypothesized that the sex differences would appear even greater, with fathers attributing even less fear to their sons than to their daughters. Whether made by parents or by children, the reports are based on unsystematic observations that are subject to many biases, and the respondents' recall is subject to many distortions. Neither test–retest reliability nor validity measures are routinely taken.

Although normative studies have been reported since 1932, their results are not generalizable because random sampling from the normal child population is seldom attempted. With very few exceptions (e.g., Lapouse & Monk, 1959; L. C. Miller et al., 1971), these are not properly normative studies. Investigators appear to have been interested in limited segments of the population or were restricted in terms of the availability of subjects. For example, some studies (Marks & Gelder, 1966; Poznanski, 1973) used samples drawn from psychiatric populations, and Maurer (1965) used children referred to school psychologists. Abe (1972) obtained data from a self-selected population of young mothers who were patients in a free medical clinic in Japan; Bamber (1974) studied children in Ireland; and Pratt (1945) studied only rural children.

In summary, the basic subjective-report methods have obvious shortcomings: some studies interviewed children, some parents; some required lists, some ratings; the ages of children are not comparable across studies; random samplings from normal childhood populations were seldom taken; reliability and validity data were not reported.

But the major limitation in all of this research is the nature of the questions that have typically been asked. The studies have been virtually limited to identifying fear stimuli, to asking, essentially, "*What* are the common fears of children?" and "To what demographic factors do they relate?" Most studies seem still to be trying to accomplish Hagman's (1932) first aim, that is, "to enumerate and analyze the objects and situations feared" (p. 110). It seems clear that many factors influence the objects or situations chosen as fear stimuli. Some stimuli, as Maurer (1965) pointed out, seem to be merely the subject of the latest adventure story or movie to which the child was exposed; others seem to be stereotypes or culturally conditioned fears, and still others appear to have some significance for the child's life (e.g., Angelino et al., 1956; Maurer, 1965). The type of identification and tracking of fear stimuli that has been done could probably be continued indefinitely. However, the question must be raised as to the point

of such an enterprise. In an area as broad and important as fear in children one must ask oneself what kind of research is worth doing and what kind of knowledge is worth having.

The identification of fear stimuli touches on only a small part of what must be a complex fear process. It seems reasonable to assume that children's fears, like other human reactions, proceed through complex paradigms—from fear stimuli that vary in number, type, and intensity and that may be internal, external, or both; through emotional and cognitive operations within the child; through overt fear responses that may act upon and modify both the social and physical environment and that themselves, by means of feedback loops and chaining, may occasion variations in any part of the process. The processes themselves may further vary with developmental factors. Given this reasonable assumption of human complexity, it is clear that the normative research to date has ignored a great deal of it, limiting its view to only one part of the process, that is, identifying fear stimuli. It is as if early researchers took the first reasonable steps toward learning what it is that children typically fear, but then allowed the field to remain on that level, the researchers generating, sharing, and rearranging virtually the same lists of fear stimuli. The research tells us little about the remainder of the paradigm, the nature of children's fear experiences. Remaining unasked are questions concerning the operation of mediating cognitions in children's fear experiences, the degree to which fears are self- or externally generated and maintained, and the effects of fear behavior on the child's social environment and the effects' feedback influence on the child. One must investigate how children in their natural environments typically deal with fearful events and how their strategies vary with developmental level, sex, and so on. One must study the conditions under which natural coping processes fail and fear processes become debilitating, and one must determine the optimum conditions for fear-reduction intervention.

We suggest, too, that there is a related, potentially important issue that has thus far been ignored in the literature: the recognition of the possible adaptive value of childhood fear. Of course one has no clear indication that fear serves any adaptive function at all. But it may be that age-linked, transitory fears have important short-term effects on coping with the social environment, on learning how to appropriately sensitize and desensitize oneself. Fear may constitute an important part of children's experiences in learning to successfully cope with problems. The possible adaptive value of fear experiences in children's development may be an important issue, but has been overlooked, clouded perhaps by an implicit, unquestioned value judgment that fears are only disruptive and hence are of negative value.

A great variety of stimuli have been identified as having fear-stimulus value; they range from specific objects (e.g., bees) to abstract and imaginative stimuli such as communism and ghosts. As pointed out by Berecz (1968) and L. C. Miller et al. (1974), almost any event may be a potential fear stimulus. Thus children have access to an inexhaustible supply of them. The normative research suggests that "normal" fear stimuli for children are socially determined and are appropriate for the individual's personal and social situation; for example, the elderly fear loneliness and physical injury, students fear examinations, lower SEC boys fear switchblades and beatings, and young children, still learning the limits of reality, fear ghosts, witches, and darkness. The fears are appropriate to age, social class and role, culture, and even moment in history. Thus the normative data suggest that what is feared by children is largely determined by social and historic fashion as well as by individual experiences. Although some fears may be innately determined, it appears that children fear largely what they are taught to fear. It seems that identification of fear stimuli may be limited in its contribution to understanding the processes of learned fears in children, since so many stimuli may be interchangeable. Further research in this direction is of doubtful value, and attention to other parts of the complex fear paradigm would be more profitable. Overall, the normative research only suggests, and with a good amount of conflicting data, that the type

and number of fears vary with age, sex, and SEC. The details of the apparent relationships, however, are not clear. There is conflicting evidence concerning the relationship of fears to pathological behaviors, and there are virtually no data on the intensity of fear reactions. The normative research reveals very little beyond the findings of what appear to be a few key studies (e.g., Jersild & Holmes, 1935a, 1935b; Lapouse & Monk, 1959; L. C. Miller, Barrett, Hampe, & Noble, 1972a; L. C. Miller et al., 1972b). The "disappointing research" (Berecz, 1968) may be at least partly due to the ethical problems of fear research with children as well as to a variety of methodological problems that characterize the research. Because of its apparent fixed focus on identifying fear stimuli, the research tells one little about the complete fear processes.

Case Studies of Fear Reduction

Like other aspects of the literature in this area, fear-reduction experimental and case studies have a long history. According to Yates (1970), most of the techniques that are now labeled *behavior therapy* were applied in one form or another some 50 years ago, almost entirely in attempts to treat children's fears. Watson and Rayner (1920) suggested, but did not investigate, four possible methods to remove the fear that they had conditioned in Little Albert. Jones's (1924b) treatment of Peter is an early example of the application of learning principles to the remediation of clinical problems. Jones (1924a) studied 70 children in an attempt to discover ways in which children's fears could be reduced or removed. Holmes (1936), stressing the importance of active participation by the child, attempted to eliminate fears of the dark and of heights, whereas Hagman (1932) and Jersild and Holmes (1935b) reviewed methods that parents actually used to deal with fears and suggested a number of more effective techniques.

Unfortunately, as with the normative studies, the promise of the early work was not fulfilled. The vigorous interest in treatment of children's fears seemed to disappear, and except for a few case studies, there was little further activity until Rachman and Costello's (1961) review of the etiology and treatment of children's phobias. They called for "above all a major project to establish the degree and permanence of improvement which may be obtained by these techniques" (p. 104) (i.e., those suggested by Jones, 1924a, 1924b, and by Jersild & Holmes, 1935b). This call has also gone largely unanswered. The amount of research in the behavioral treatment of children's fears since that time has been surprisingly meager in comparison with the amount of behavioral research on adult fears, an area with well over 100 outcome studies on systematic desensitization alone (Wolpe, Brady, Serber, Agras, & Liberman, 1973).

Most of the reports on childhood fears are single-case studies, with all of their attendant limitations. However, case studies may offer something that experimental studies do not, that is, examinations of children's phobias at high levels of severity, and may give hints about the nature of phobias and treatment suggestions.

Prior to 1960 there were only a few behaviorally oriented case studies of child fear reduction (e.g., Jones, 1924b; Rodriguez, Rodriguez, & Eisenberg, 1959; Weber, 1936). Since 1960 at least 35 additional papers have appeared, which report on 112 children referred for clinical treatment. Of these papers, 20 were limited to school phobias and account for 72 of the cases. The remaining 15 case studies, accounting for 40 children, involved school phobias plus a variety of other fears. Thus, since 1960, excluding school phobias, all other children's fears averaged about 2 case studies per year, a strikingly low average compared with the rest of the behavior therapy field.

Considering the variety of fears reported in normative studies and included in fear surveys, the range of phobias that are presented for treatment is quite small. The overwhelming majority of reported cases involve school phobia, followed by those involving fears of animals, noise, and bodily injury. Even assuming that most of these clinical cases represent severe levels of fear, we note that both the range and the number of severe fears presented for treatment are

relatively small. Thus, the important question remains unanswered: Are severe fears largely undetected, or do they simply not occur at a very high rate?

The school phobia literature has been reviewed (Gelfand, 1978; Hersen, 1971; Kelly, 1973), and this section is presented only as a brief overview. School phobia is more prevalent than other childhood phobias (L. C. Miller et al., 1974), a fact that may be due to the high cultural value and legal requirements placed on school attendance. Because it is socially and legally less acceptable for a child to avoid school than to avoid dark places, small animals, and so on, more school phobia cases are likely to be referred for clinical help, that is, the school-phobic child conflicts with social convention more visibly and inconveniently than other fearful children.

Previous reviews suggest that the prognosis for improvement is good with most types of treatment, provided that school refusal has not yet become a chronic pattern. Behavior therapy procedures for school phobia generally are based on both classical and operant conditioning models. Thus, school phobia is seen as avoidance behavior motivated by high anxiety and maintained by reinforcement for not attending school. Four major respondent-based procedures have been reported: (a) systematic desensitization (Chapel, 1967; Lazarus, 1960; Lazarus & Abramovitz, 1962; P. M. Miller, 1972); (b) in vivo desensitization (Garvey & Hegrenes, 1966; P. M. Miller, 1972; Olsen & Coleman, 1967; Tahmisian & McReynolds, 1971); (c) flooding (Kennedy, 1965); and (d) implosion (Smith & Sharpe, 1970). Three major operant conditioning procedures were reported: (a) home-based contingency management (Ayllon, Smith, & Rogers, 1970; Cooper, 1973; Edlund, 1971; Hersen, 1970; Kennedy, 1965; Vaal, 1973); (b) school-based contingency management (Brown, Copeland, & Hall, 1974; Hersen, 1970; Rhines, 1973; Weinberger, Leventhal, & Beckman, 1973), and (c) behavioral shaping in the clinic (Hersen, 1970; Patterson, 1965). Most case studies report procedures based on combinations of the classical and operant models, with emphasis on one. The choice of which theoretical model and therapeutic procedure to use seems determined by whether the most pressing therapeutic need is to reduce the child's anxiety with a desensitizing procedure or to avoid reinforcing his or her escape behavior. Follow-up data (ranging from 4 weeks to 2 years) were reported for the majority of cases, although the data were limited either to assessment of continued school attendance or to attendance data plus a verbal report from parents and teachers on the child's social or emotional functioning. Actual behavioral assessment of improvement after return to school was not reported for any case. Whether such follow-up data should be collected is apparently still debatable. Hersen (1971) has criticized behaviorally oriented therapists for not being more rigorous in obtaining data regarding academic, social, and emotional adjustment. However, Ayllon et al. (1970) stated that "school attendance is a legitimate if not the only relevant treatment objective for school phobia" (p. 135).

Behavior therapy procedures for phobias other than school phobias are generally based on a classical conditioning model, that is, the avoidance is seen to be mediated by high anxiety. Two main approaches are used to reduce the inferred mediating anxiety: (a) counterconditioning procedures that pair the anxiety response with a stronger response that is also antagonistic to anxiety, such as muscular relaxation, and (b) extinction procedures in which the anxiety response is repeatedly elicited, but presumably without reinforcement. Therapy for these phobias usually involves a combination of several procedures. The terminology used for the procedures is confusing and overlapping, but the various authors claim that real differences do exist, as summarized by the following four categories: (a) reciprocal inhibition (Bentler, 1962; Freeman, Roy, & Hemmick, 1976; Jones, 1924a; Katz, 1974; Lazarus & Abramovitz, 1962; Miklich, 1973; Ney, 1968; Tasto, 1969; Wish, Hasazi, & Jurgela, 1973), (b) contact desensitization (Weber, 1936), (c) implosion/flooding (Ollendick & Gruen, 1972; Smith & Sharpe, 1970), and (d) in vivo desensitization plus guided practice (Croghan & Musante, 1975). In cases using reciprocal inhibition, the following responses antagonistic to anxiety were used: feeding (Jones, 1924a), muscle relaxation (Tasto, 1969),

playing (Bentler, 1962; Ney, 1968), and emotive imagery (Lazarus & Abramovitz, 1962). Interestingly, playing was included as an integral part of several treatment procedures (Bentler, 1962; Croghan & Musante, 1975; Ney, 1968; Weber, 1936). However, none of these authors stated explicitly that playing was used to teach the child skills of interaction with the feared stimulus. This lack of emphasis on skills training in case studies is interesting in light of Rimm and Masters's (1974) suggestion that therapists not place sole reliance on decreasing anxiety through desensitization techniques when working with socially inexperienced young children, who often lack the appropriate behavioral skills required to cope with the feared stimulus. Follow-up data were reported in 10 of the 15 recent papers. However, such data were rarely behavioral, making comparisons among cases regarding long-term effectiveness difficult, if not impossible. Rather, follow-up data were obtained in verbal reports of parents or teachers regarding the child's maintenance of his or her new approach behavior.

In summary, we can draw the following tentative conclusions about the clinical treatment of childhood phobias, as reported in case studies. First, given the strikingly low number and narrow range of reported cases, it seems that childhood phobias may not be a significantly large clinical problem, except for school phobia. Second, excluding school phobia, the most frequently used therapy procedures are modifications of those used with adults, that is, systematic desensitization and implosion/flooding. As has been noted elsewhere (Graziano, 1975), serious ethical and humanitarian questions are raised in using implosion/flooding techniques on children, because children generally have no choice in whether to enter and remain in therapy. Furthermore, as Ullmann and Krasner (1975) have cautioned, the successful use of implosion techniques requires considerable clinical skill and sensitivity so that the highly aversive treatment experience is associated with the avoided object and not with the therapist. In contrast with other phobias, school phobia is again an exception in that its treatment procedures generally include the use of both classical and operant techniques. Thus, this set of case studies may be taken as a comment on the state of the field: With the exception of school phobia, the clinical importance and prevalence of childhood phobias is questionable, and the procedures used are generally copied from work with adult phobics.

Important therapy and research questions raised by these case studies appear to fall into three main categories. First, what procedures not generally used with adults might be useful with children? As noted by Rimm and Masters (1974), young children often lack the appropriate behavioral skills required to cope with the feared stimulus. Thus, the absence of much if any overt skill training in the case reports seems a glaring omission. Such skill training might take the form of guided participation or modeling. Second, what treatment combinations are most effective and efficient for different kinds of phobic children? As pointed out by both Berecz (1968) and Hersen (1971), more controlled research designs are needed to adequately test both the efficacy of any one procedure and the conditions under which it will be most effective, both alone and in combination with other procedures. Case studies are limited in two senses: (a) One has no way to know whether other attempts to treat a phobic child by these authors or other authors using similar techniques were unsuccessful (i.e., how unique is the success of this procedure?); (b) we cannot compare the effectiveness of two or more different procedures because most reports use language that cannot be interpreted in terms of specific behavioral gains (e.g., "has remained in school and continued to improve"). Thus, despite the difficulties, a clear need still exists for more controlled designs using experimental groups or highly systematic multiple studies. Finally, these case studies raise the question of what criteria for success should be used, both at treatment termination and at follow-up. Should one assess only improvement in approach behavior? Or should one also assess improvement in social and emotional functioning? One rationale for collecting social and emotional adjustment data is that these data might help researchers make comparisons among the various techniques, with the

ultimate aim of identifying the most rapid and widely effective combinations. At any rate, termination and follow-up data should be collected and reported in terms of behavioral observations as well as in terms of verbal reports from parents and teachers.

Controlled Fear-Reduction Studies

At least 28 controlled fear-reduction studies with children have been published, and there are several additional unpublished papers such as those reported in Gelfand's (1978) review. Although far more rigorous and systematic than the clinical case studies, the controlled studies share several common limitations. First, with few exceptions (e.g., L. C. Miller et al., 1972a; Obler & Terwilliger, 1970), they study what appear to be mild to moderate levels of fear, and the relevance of their findings for treating children with severe fears or phobias has yet to be demonstrated. Second, as with the case studies, the range of fears included has been limited: 9 studies focused on dental/medical fears (Adelson & Goldfried, 1970; Adelson, Liebert, Poulos, & Herskovitz, 1972; Johnson & Machen, 1973; Machen & Johnson, 1974; Melamed, Hawes, Heiby, & Glick, 1975; Melamed & Siegel, 1975; Melamed, Weinstein, Hawes, & Katin-Borland, 1975; Vernon & Bailey, 1974; White & Davis, 1974). Animal fears were discussed in 7 studies (Bandura et al., 1967; Bandura & Menlove, 1968; Hill, Liebert, & Mott, 1968; Kornhaber & Schroeder, 1975; Murphy & Bootzin, 1973; Obler & Terwilliger, 1970; Ritter, 1968). Fears of social interaction were discussed in 5 studies (Evers & Schwarz, 1973; Keller & Carlson, 1974; O'Connor, 1969; O'Connor, 1972; Walker & Hops, 1973). Three studies focused on fears of the dark (Kanfer et al., 1975; Kelley, 1976; Leitenberg & Callahan, 1973). Two discussed test anxiety (Mann, 1972; Mann & Rosenthal, 1969), and 1 studied fear of water (Lewis, 1974). L. C. Miller et al.'s (1972a) study included a variety of fears, such as fear of school, the dark, heights, germs, nakedness, and storms. However, if one deletes school phobics, the number of children in L. C. Miller et al. who presented fears other than those typically studied totals only 11.

Another general limitation is that most studies use a number of different techniques in complex treatment packages, and it is usually not possible to determine the most effective components of the packages.

The profusion of concepts and methods makes it difficult to organize these studies for discussion. They present a variety of terms, including desensitization, extinction, modeling, reciprocal inhibition, and so on. It is frequently unclear whether a term, systematic desensitization, for example, is used to denote a treatment procedure and is thus part of the independent variable or whether it refers to implicit processes of fear reduction within the child and is thus part of the dependent variable. Likewise, apparently similar processes or procedures are labeled differently by different authors, such as Ritter's (1968) "contact desensitization" versus Lewis's (1974) "participant modeling."

Most authors make their procedures fairly explicit, but only imply their models of fear-reduction processes. However, it appears that all of these authors assumed a disinhibition model, that is, the operation of some process of gradual weakening of the fear response in the course of graduated exposure to the fear stimuli. The graduated exposure may occur actually, imaginally, or vicariously.

The methods used to operationalize gradual exposure fall into three main groups: (a) modeling, (b) multivariable, systematic desensitization or contingency management treatment packages, and (c) a cognitive approach using verbal-mediation strategies. By far, modeling is the most frequently used procedure, accounting for 20 of the 28 controlled studies. Many of the remaining 8 papers seem to have included some forms of modeling, but did not label them as such. Modeling may be implicit in any of the fear-reduction procedures except, perhaps, for imaginal systematic desensitization.

Modeling

Modeling is largely a development of the last decade; it was stimulated by Bandura's research (e.g., Bandura et al., 1967; Bandura & Menlove, 1968), although precursors of modeling are clearly seen in Jones (1924a).

At least 20 modeling studies of fear reduction in children have been published in the past 10 years. Although there are clear similarities among them, they fall into two fairly distinct groups with a number of important differences. Of these studies, 11, including Bandura's research, dealt with fairly common fears that occur frequently, even daily, for many children in the course of everyday events (i.e., fear of animals, the dark, water in baths, school examinations, and social interactions). In most instances the fears are clearly unreasonable, in that there seems to be nothing objectively harmful in the immediate situation. The other 9 studies form a distinct group of recent research published in the 1970s. They focused on the specific problems of reducing children's fears and preparing them for dental and surgical procedures. Unlike those in the former group, these fears are highly situation-specific and include often intense, but transitory, anxiety; they occur only at those few times when children are faced with dental or surgical procedures and thus, unlike many other fears, are not frequent or everyday issues. Also, the fears in this group appear more reasonable or reality based than, for example, fears of the dark. It does not appear to us to be at all unreasonable for a child to struggle against a dentist or surgeon who is going to do unexplained things that, as far as the child knows, will probably hurt a great deal. In fact, we would argue that such self-defensive assertion on the part of a frightened child who is psychologically unprepared for the coming medical treatment is preferable to quiet, but totally frightened, submission. This group of modeling studies focused on the reduction of such fears in these specific situations. They may thus be of immense potential importance for untold numbers of children.

One of the studies in this group (see the listing above) is Melamed and Siegel's (1975) excellent research using symbolic modeling procedures to prepare children psychologically for surgery. The experimenters used a 16-minute film of an initially fearful child who gradually copes with the situation and overcomes his or her own fears. They reported that the children who viewed the modeling film, compared with control group children, showed significantly less "transitory, situational anxiety" on all measures (sweat gland activity, self-reported medical concerns, and overt, anxiety-related behavior). Their data also suggested that experimental group children had fewer postoperative behavior problems than did the control group children.

These 9 studies give good evidence that brief symbolic modeling may be an effective aid in preparing children for dental and medical treatment, thus reducing their possibly high situational fears. The studies are limited to some degree in that they studied groups of normal children and did not include dental or medical phobics per se, and thus one cannot generalize these results to such chronically fearful children. Further, there is little evidence of the long-term effects of such modeling and yet no differential study of the effect of variables such as cognitive rehearsal, model and subject similarity, age, and so on. But all of those limitations can be avoided in future research.

In all of these studies the strategy was a preventive one; that is, prior to the occurrence of the stressful situation, children were prepared so they could more effectively cope with the stress when it did occur. There are important implications here for preventive and "stress inoculation" approaches, as is briefly discussed later.

Overall, the quality of these 20 modeling studies is high, but generalization are limited for a number of reasons. First, none of the studies typically included severely fearful children, although Bandura and Menlove (1968) did describe fairly high levels of dog fear in some children, and many of the subjects in the dental/medical fear-reduction research seemed quite fearful. Overall, the children were not selected for severe or phobic levels of intensity or duration of fears. Although modeling appears to be quite effective with mild to moderate fears, its usefulness in reducing phobias or severe fears has not yet been shown. In order for modeling to be effective, the child must attend to the model. Children who are highly fearful may find watching any interaction with the phobic stimulus so aversive that they look away, thus avoiding the fear stimulus. Bandura and Menlove (1968) commented on encoun-

tering a similar difficulty. Thus, successful modeling with severely fearful or phobic children has yet to be demonstrated.

All of the studies used behavioral avoidance tests or behavioral observations in their pretreatment assessments. These procedures separate children by fear levels in comparison with other children in a particular study, but do not assess the clinical significance, per se, of the fears. Further, although the subjects' age range was wide (3–13 years), selective factors may have operated, for example, the use of children from special university nursery schools (e.g., the Bandura studies) or from parochial schools (e.g., Kornhaber & Schroeder, 1975) or the use of only black children (e.g., Lewis, 1974) or only poor center city children (Melamed, Hawes, Heiby, & Glick, 1975). Thus, the subjects in the experimental studies of modeling are not representative of either a clinical population or the normal population of children.

As noted earlier, the range of fears to which modeling has been applied is limited, with nine studies focusing on fears of impending dental/medical treatment, six on animal fears, four on social isolation, and one on fear of water. Thus one must be cautious about generalizing from these modeling studies either to the general or clinical populations or to different fear stimuli.

The basic modeling approach common to these studies consists of fearful subjects' first observing models who demonstrate approach to the fearful stimuli. The subjects then attempt to perform the approach behavior themselves. This basic method has been varied across several dimensions: The modeling has been symbolic, as on videotapes (e.g., Bandura & Menlove, 1968; O'Connor, 1972), or presented by live models (Bandura et al., 1967; White & Davis, 1974); subjects have observed a single model (Ritter, 1968) or multiple models (Bandura & Menlove, 1968); modeling alone has been compared with modeling plus active, graduated contact with models and the fear stimulus (Lewis, 1974; Murphy & Bootzin, 1973; Ritter, 1968); the models have approached single stimuli (e.g., Kornhaber & Schroeder, 1975) or graduated variations of the fear stimulus, such as Bandura and Menlove's (1968) use of a variety of dogs; and the similarity of models to subjects has been explored (Kornhaber & Schroeder, 1975).

Not all of the meaningful combinations of these and other variables have yet been examined, nor have sufficient replications of successful studies been carried out. However, some clear consistencies and at least tentative conclusions have emerged. First, therapeutic modeling procedures are in general significantly more effective than control conditions and can override pretreatment differences in "predisposition to emotionality" (Bandura & Menlove, 1968) and in model's similarity to the subject (Kornhaber & Schroeder, 1975). Further, modeling procedures seem effective over a fairly wide age range.

Second, the research suggests that modeling procedures become more powerful as additional controlled components are added to the basic techniques. Thus it seems likely that a highly effective modeling package would include multiple live models who approach a hierarchical range of varied fear stimuli, followed by trials of active contact with models in graduated sequences of progressively bolder contact with the graduated fear stimuli (Murphy & Bootzin, 1973; Ritter, 1968), that is, a modeling plus contact-desensitization package. There is considerable agreement that live modeling combined with progressive contact with models and fear stimuli is potentially a very powerful technique. To date, however, the complete modeling package outlined here has not been tested either against control or against other modeling procedures.

Third, although live modeling appears to be more effective than symbolic modeling, the latter may be equally effective (Bandura & Menlove, 1968) if it involves many trials and includes multiple models and progressively varied fear stimuli. In other words, a symbolic modeling package similar to that described above for live modeling may also be a powerful fear-reduction technique. The significance of this lies in the potential use of symbolic modeling procedures in large-scale fear-reduction projects, in which direct contact with large numbers of children is not feasible. Thus, to the degree that children's fears may be a large-scale problem, symbolic

modeling may offer potentially useful remediation. As of now, the effectiveness of such a program presented, for example, in educational television broadcasts, has not been tested and remains only a possibility.

Fourth, symbolic modeling has important implications for immunological approaches (e.g., stress inoculation; Meichenbaum & Turk, 1976). Although Bandura and Menlove (1968) pointed out the possibility of such preventive strategies as early as 1968, only recently have such approaches been applied to children's fears. Poser and King (1975) reported on a series of their experiments on the reduction of avoidance. In every case, the avoidance inhibitor was brought to bear before rather than after avoidance responding had occurred. One experiment made use of symbolic modeling to inhibit the acquisition of snake avoidance responses in first graders confronted with a live snake for the first time. These approaches deserve much more attention. For example, as is suggested by studies such as O'Connor's (1972), might it not be possible to "immunize" entering kindergarten or nursey school children against early school fears? The symbolic modeling studies on reducing dental/medical fears also have clear implications for fear prevention. Large-scale televised symbolic modeling is a potential preventive strategy that has important community mental health implications. It is an area well worth careful attention.

Fifth, some dimensions of model and subject similarity may be important. Kornhaber and Schroeder (1975) found that age similarity (peer modeling) was associated with greater fear reduction for children than was adult modeling, although neither attitudinal nor behavioral similarity was an effective variable. Although researchers have investigated model–subject similarity with regard to other behaviors (e.g., Bandura & Barab, 1973; Bandura, Ross, & Ross, 1973; Baron, 1971; Hicks, 1965; Maccoby & Wilson, 1957; Wheeler & Levine, 1967), only Kornhaber and Schroeder (1975) have manipulated model similarity in child fear reduction. Clearly this issue—the relationship between model and subject similarity and the reduction of children's fears—is an area in which more research is needed.

Sixth, Kornhaber and Schroeder (1975) and Melamed and Siegel (1975) also touched upon a related and possibly important issue, that is, the relative effectiveness of models' portraying a *mastery* versus a *coping* strategy in fear reduction. Several authors (Blanchard, 1970; Rachman, 1972; Ross, 1970) have suggested that modeling effectiveness might be increased if models demonstrated initially fearful behavior that gradually changed to fearless interaction with the stimulus. Hill et al. (1968), Melamed and Siegel (1975), Meichenbaum (1971), and Spiegler, Liebert, McMains, and Fernandez (1969) all had their models exhibit some fear during the initial approach. Using adult subjects, Meichenbaum (1971) directly compared coping (initial display of fear) and mastery (no fear modeled) strategies. Meichenbaum found greater fear-reduction effectiveness with the coping strategy than with the mastery strategy. However, in all three studies there was sufficient confounding of variables to make their results uncertain. In the Meichenbaum study, for example, the coping models—but not the mastery models—also demonstrated a breath-control relaxation technique that may have accounted for many of the differences.

Although Kornhaber and Schroeder (1975) compared a coping and a mastery modeling procedure, their coping models displayed fear throughout the modeling and did not demonstrate a progressive reduction of fearful behavior that matched the demonstration of increased approach. Their coping model was thus incomplete. Finally, the coping model procedure used by Melamed, Hawes, Heiby, and Glick (1975) and Melamed and Siegel (1975) was part of the modeling package applied to all experimental subjects and was not compared with a mastery model condition, thus making it impossible to assess the effects that can be attributed to coping strategies per se. To date no researchers have systematically investigated and carefully compared coping versus mastery modeling procedures in child fear reduction. This is an obvious area in need of research.

Seventh, although modeling procedures appear to be of a decidedly social nature, they seem to have rarely been used to reduce basically social fears of children such as

shyness, severe isolation, fear of speaking in groups, and so on. An exception is O'Connor's (1969, 1972) work with socially withdrawn nursery school children. Using only a 23-minute peer-modeling film that showed progressively more involved social interactions, O'Connor reported dramatic changes in originally shy nursery school children. The children reportedly became normally assertive in class and "indistinguishable" from their nonshy classmates after only one viewing. Control children did not change. O'Connor's results are extremely impressive, but, as discussed by Gelfand (1978), a number of subsequent attempts have failed to demonstrate positive effects of symbolic modeling on social withdrawal. The experimenters, nearly all in unpublished papers, attempted to explain their lack of success by pointing to their own procedural shortcomings (e.g., too disparate model-subject ages, lack of a sound track to accompany a modeling film, a failure to clearly model coping strategies, etc.). These failures suggest that modeling may not be as powerful and reliable a technique as in suggested by the published studies. It is most interesting that the attempts to account for the failures suggest a possibly strong presumption of the effectiveness of modeling strategies, a presumption powerful enough to necessitate explaining away the failures as experimental weaknesses. In other words, there may be a tendency to discount negative evidence on modeling.

One of the successful modeling studies on social withdrawal (Jakibchuk & Smeriglio, 1976) reported that the videotaped model's use of a first-person narrative in which the child described himself or herself as initially shy was essential. Their work suggests the operation of important cognitive factors through first-person self-statements as well as the importance of the model's behavioral similarity to the observing child.

Finally, even when modeling is successful in modifying fear behavior, the effects of modeling may disappear in a few weeks for adults (e.g., Bandura, Jeffery, & Wright, 1974) and for children (Keller & Carlson, 1974) if subsequent reinforced practice is not made available to the observer. Like other behavior modification techniques, particularly those used in the 1960s (Graziano, 1975), modeling with fearful children has repeatedly demonstrated its success in modifying target behavior; but there are yet few data on either the generalization or the maintenance of the new behavior. Further research on these two issues is necessary.

Overall, despite some negative evidence and many yet unanswered questions, the bulk of the research evidence supports modeling as an effective set of techniques and a rich area for further research. Needed are systematic examinations of the effects of several variables (e.g., model and subject similarity, coping and mastery strategies, single and multiple modeling, etc.). Three of the more important questions to be answered concern (a) the intensity of fears for which modeling might be effective, (b) the potential use of large-scale symbolic modeling to reduce and, perhaps of greater importance, to prevent particularly common and disruptive fears, and (c) the generalizability and maintenance of behavior newly achieved through modeling. Conspicuously absent in the modeling research to date is direct investigation of the degree to which cognitive factors such as covert competency self-statements are operative.

Desensitization and Contingency Management Packages

Seven studies describing complex treatment packages are included here. Two studies (L. C. Miller et al., 1972a; Obler & Terwilliger, 1970) included children with severe fears. Two other studies (Mann, 1972; Mann & Rosenthal, 1969) studied adolescents referred by school counselors for test anxiety who could also be considered at or near severe levels. Obler and Terwilliger used systematic desensitization to pictures of fear stimuli followed by up to 50 hours of in vivo contact desensitization to reduce the severe monophobias (of dogs or buses) of 30 "neurologically impaired" children.

L. C. Miller et al. (1972a) compared reciprocal inhibition, psychotherapy, and a waiting-list control condition as treatments in phobic children. The reciprocal inhibition treatment condition was actually a broad array of behavioral approaches, including

meetings with parents, restructuring home contingencies, assertive training, relaxation and systematic desensitization, and discussions of problems and progress. The psychotherapy treatments focused on inner experience and encouraged the child to talk about his or her feelings and conflicts. There seems to have been considerable overlap in these two treatment conditions: For example, discussions with parents and altering home conditions are similar strategies; and denying the child in the reciprocal inhibition group free access to television at home ("restructuring contingency schedules") to decrease the reinforcement for fear behaviors is similar to the strategy of "removing gratifications" so as to reduce "secondary gains."

Their results are complex and difficult to summarize. Overall, neither treatment was more effective than the waiting-list control treatment. However, when age is considered, the reciprocal inhibition and psychotherapy treatment conditions were equally more effective than the control conditions for children 10 years of age and younger, whereas those 11–15 years old did not seem to respond to either treatment condition. In a 2-year follow-up (Hampe et al., 1973) the investigators found major effects of age and elapsed time. The younger children had "changed dramatically" immediately following treatment and maintained their improvement. Older children showed a more gradual improvement over the 2-year follow-up, as did control children. The researchers concluded that age and time are critical factors in child fear reduction. Younger children tend to lose their fears much more rapidly than do older children; in time (up to 2 years), children generally lose their fears with or without treatment; nevertheless, treatment, behavioral or psychodynamic, is justified because it "greatly hastens recovery" (p. 451).

Both studies, particularly Obler and Terwilliger's, employed complex treatment packages. Although both research groups labeled their major procedures *systematic desensitization* (Obler & Terwilliger, 1970) or reciprocal inhibition (L. C. Miller et al., 1972a), that is, some variation of Wolpe's (1974) systematic desensitization, they both also included a variety of contingency management techniques, including shaping and probably some modeling. Neither study clearly specified the roles of the therapists, and it is difficult to know just what occurred in the various treatment groups. Further, both studies used parents' reports as the major dependent variable. In fact, Obler and Terwilliger based their analysis on a single item from a 10-item parents' questionnaire. As critiqued by Begelman and Hersen (1971), Obler and Terwilliger's study has methodological problems that make its positive findings highly questionable. L. C. Miller et al. (1972a) and Hampe et al. (1973) are useful studies, in spite of the difficulties noted above. They present important findings concerning fear reduction as a function of age and time, and they include a long-term (2-year) follow-up, a rare occurrence in behavioral research. In essence these three studies together fail to support the differential effectiveness of complex systematic desensitization treatment packages for either severe or more moderate fears. From L. C. Miller et al. and Hampe et al., the safest conclusion is that either behavioral or psychodynamic treatment is helpful in the short term for younger children, who in any event apparently would overcome their fears without treatment in the long (2 years) term.

The articles by Leitenberg and Callahan (1973) and Kelley (1976) are clinical analogs focused on nursery school and kindergarten children selected for their fear of the dark. Both studies were well designed and used control groups, duration of dark tolerance as pre- and posttreatment behavioral measures, and visual "fear thermometers" for subjective reports by or feedback to the subjects. Neither study employed a follow-up, and no attempt was made to assess the clinical severity of the fears, leaving the possibility that the subjects were only mildly to moderately fearful.

Leitenberg and Callahan used a "reinforcement practice" method in which children were instructed to remain in a dark room for longer periods of time over five trials per session and two practice sessions per week for a maximum of 4 weeks or until the child reached a criterion of two consecutive 5-minute dark-tolerance trials. For each suc-

cessful trial the children were reinforced with praise and prizes. The authors reported a significant treatment and control group difference on posttraining dark-tolerance tests. However, there were only seven children in each group, and the mean posttraining dark tolerance for the experimental group was only about 3 minutes. Although statistically significant, does a 3-minute dark tolerance have any personal or clinical significance?

Kelley (1976) assigned 40 children who feared the dark to three desensitization treatment groups, one "play placebo" control, and one no-treatment control group and reported no differences between treatment and controls or among the three treatment conditions. The most important finding of this study is the significant effect of a simple demand manipulation, that is, verbal instructions to remain longer in the dark room dramatically increased dark tolerance and was "a far more powerful influence on both behavioral and self report change scores than three sessions of therapy" (Kelley, 1976, p. 80). In light of Kelley's findings and their implications, we suggest that Leitenberg and Callahan's "significant" reinforced practice effects may have been due simply to their verbal instructions to the experimental group only to remain in the dark room for a longer time on each subsequent trial. Kelley's finding is particularly important because it seems reasonable to hypothesize that demand characteristics are especially salient to children who, because of their immature status, are often in the position of having to comply with the outright and sometimes subtle demands of adults. Certainly these issues need to be explored. The critical research has not yet been done, but it may be that dark-tolerance performance of dark-fearful children can be significantly improved by instruction alone. But would this manipulation, perhaps over repeated trials, change other aspects of fear such as physiological and cognitive responses, and would those changes hold up over time? A potentially important area in need of research is the effects on children's fear behavior of adults' instructions.

In two studies, Mann and Rosenthal (1969) and Mann (1972) compared direct and vicarious desensitization procedures in the reduction of adolescents' text anxiety. Like subjects in Obler and Terwilliger (1970) and some of those in L. C. Miller et al. (1972a), these adolescents, referred by a school counselor for high test anxiety, appear to have been severely fearful. Their major finding was systematic desensitization, whether applied individually or in groups, whether actually or vicariously experienced, was significantly more effective in reducing test anxiety than the waiting-list control condition. The control subjects, when treated later, also improved.

Most interesting about Mann's studies is that the most effective procedure was a vicarious desensitization condition, which actually sounds very much like a symbolic modeling procedure in which subjects observe a videotaped peer model undergoing systematic desensitization and gaining control over the fear. The subjects in the vicarious condition showed greater improvement than those who actually experienced direct systematic desensitization! In Mann's work, then, although called a *desensitization* procedure, the symbolic modeling approach was the most effective with apparently highly fearful subjects. In effect, these two studies of desensitization support the effectiveness of symbolic modeling.

In three modeling studies of shy or withdrawn children, investigators tested whether the addition of direct shaping procedures added any power to the basic symbolic modeling procedure. Evers and Schwarz (1973) found that it did not. O'Connor (1972) reported that although shaping (with praise and attention) was as effective as symbolic modeling, the new interactive behavior of the shaping group soon decayed, whereas modeling group subjects maintained their gains. Somewhat similar findings were reported by Walker and Hops (1973). In their study, the addition of contingency management (tokens for increased classroom interaction) following the symbolic modeling film reliably increased social behavior beyond that produced by modeling alone. However, as Gelfand (1978) pointed out, when tokens were withdrawn, the new behavior degenerated. Apparently, "natural" reinforcers in the classroom did not maintain it. Perhaps a more gradual thinning of reinforcements or the use of more social

reinforcements would have produced a more stable level of interaction. The point here is that the success of contingency management techniques in reducing withdrawn or shy social behavior is still uncertain.

In summary, seven studies have examined complex desensitization or contingency management treatment packages in the reduction of children's fears, and several other studies have included contingency management procedures in addition to basic symbolic modeling approaches. Overall their findings are equivocal. One study (L. C. Miller et al., 1972a) found no overall beneficial effects of systematic desensitization compared with other treatments and with nontreated control conditions. Obler and Terwilliger's (1970) study has a number of methodological problems that cast doubt on their conclusions. Kelley (1976) reported no effects of desensitization treatment compared with two control treatments. Leitenberg and Callahan's (1973) results are based on a very small number of subjects and, as discussed earlier, are open to the interpretation that treatment differences may have been due simply to direct instructions. Mann and Rosenthal (1969) and Mann (1972) reported good results with a variety of systematic desensitization treatments, but, on close inspection, their most successful treatment appears to have been symbolic modeling rather than systematic desensitization. Finally, three of the modeling studies (Evers & Schwarz, 1973; O'Connor, 1972; Walker & Hops, 1973) found that the addition of contingency management did not usually improve performance beyond that achieved by symbolic modeling alone, and if it did, the new performance was not maintained.

Unlike in the modeling literature, there exists no convincing evidence that approaches developed on respondent-based systematic desensitization or operant contingency management paradigms are effective methodologies for reducing children's fears.

Cognitive Approaches

Only one published study (Kanfer et al., 1975) used a cognitive self-control approach in child fear reduction. Children 5 and 6 years old rehearsed one of three verbal-mediation responses: (a) sentences emphasizing the child's control or competence (e.g., "I am a brave girl (boy). I can take care of myself."); (b) sentences aimed at reducing the fear-stimulus value of the dark (e.g., "The dark is a fun place to be"); or (c) neutral sentences (e.g., "Mary had a little lamb"). In dark-tolerance posttests the "competence" group significantly outperformed the others. These children were not representative of a normal population, and they appeared to be only mildly or moderately fearful; we thus cannot generalize their results to clinical populations. The laboratory dark-tolerance test may have had no relationship to real fears in the children's natural environments, and no behavioral maintenance data were provided. However, despite some shortcomings it was a well-executed study with strong results. The operation of verbal self-control processes was suggested by the authors, although they noted that their study did not specify the details of verbal control mechanisms.

Other hints of the possible effectiveness of verbal mediation are found in case studies (Ayer, 1973; Lazarus & Abramovitz, 1962), in which children rehearsed highly competent, although very imaginative, strategies for coping with fear stimuli. The modeling research by Jakibchuk and Smeriglio (1976) suggests the necessity of a first-person self-speech narrative as an accompaniment to a symbolic modeling film. One possible interpretation of these various hints is that the children's own verbal self-instructions—whether originally received from a film, from specific sentences given to the subjects to rehearse, or from fanciful verbal and pictorial images—on how to successfully deal with the fear stimulus are a central component of the successful interventions. Although there are yet few appropriate data on the success of verbal self-controlling manipulations in child fear reduction, certainly enough data and hints are available to alert one that more research in this direction is indicated.

Summary of Controlled Studies

In summary, experimental fear-reduction research with children has been meager until the past 10 years, during which at least

28 studies have been published. Because of limited sampling procedures, their results cannot be generalized to either normal or clinical populations of children. As for the latter group, we have virtually no data and know surprisingly little about reducing severe phobic levels of children's fears. It has yet to be demonstrated whether the experimental fear-reduction findings are useful in clinical practice.

Only a limited number of different fears have been studied: fear of animals, fear of bodily injury (e.g., fear of dental treatment), fear of darkness, test anxiety, and social isolation. The levels of fear intensity have also been limited, with only 4 of the 28 studies including children with more than mild-to-moderate fears. Only 2 of the studies considered pretreatment fear duration, as a measure of seriousness. With the exception of dental/medical fears we have virtually no data on fear reduction outside of the laboratory setting and thus do not know if statistically significant changes brought about in the laboratory are related to fear behavior in the child's natural environment or are of sufficient magnitude to be psychologically or clinically significant. Although the experimental reduction of fear behavior has been repeatedly demonstrated, neither generalization nor long-term maintenance of the new behavior has been demonstrated.

Three major fear-reduction strategies have been employed: (a) Most studies (20 of the 28) have used modeling approaches; (b) 7 have used a variety of systematic desensitization or contingency management treatment packages; and (c) 1 study used a cognitive verbal-mediation strategy. Of the three strategies, the most reliably successful has been modeling (in terms of replications and fairly well-controlled methodology). A number of important research issues in modeling remain to be investigated, including model–subject similarity, coping versus mastery strategies, modeling effectiveness with severe fears, adequate demonstration of both generalization and long-term maintenance of the new behavior in the child's natural environment, and use of modeling in the prevention of fears.

A particularly important issue, not yet systematically investigated, is the operation of cognitive self-controlling mechanisms in successful modeling. Only one study used a verbal-mediation, self-control strategy. Its success is encouraging and should generate a good deal of research.

Unlike in the modeling literature, there is no convincing evidence that systematic desensitization or contingency management strategies are effective in reducing children's fears and in maintaining that reduction. Hatzenbuehler and Schroeder's (1978) recent review came to the same conclusion regarding desensitization procedures.

One of the more interesting, if still remote, practical implications of the recent research is the potential use of symbolic modeling in large-scale community mental health fear-prevention programs. A number of common, vexing childhood fears (e.g., fear of starting school and fear of dental/medical procedures) might be prevented on a large scale.

Overall, fear reduction and prevention in children, particularly using modeling and cognitive strategies, is a rich area for research and development. Many needed research directions in this field are clearly indicated.

Conclusions

Reaching back almost 60 years, the study of children's fears is old in the history of modern psychology. However, what is most striking is not the field's age but its apparent lack of progress. To paraphrase Berecz's (1968) conclusion, the literature still gives us only hints about the nature of children's fears. After what appears to have been a good start in the 1920s, the field experienced a long hiatus, which appears to be ending: The research of the past 10 years has returned to the behavior modification focus of the 1920s and early 1930s.

This review suggests that children's fears, like other human reactions, proceed through complex processes. The many variables involved and their interactions result in a complexity that provides many points at which to focus research. Briefly, fear stimuli may be internal, external, or both and may vary in content, number, intensity, and duration. The child's responses involve combinations of physiological, cognitive, and overt behavioral events, all of which may vary in latency,

intensity, and duration and with changes in stimulus conditions. The child's responses, overt or covert, may act on any of the stimulus and response variables, modify them, and thus occasion change in any parts of the process. All of these processes are immersed in social settings that contribute further sources of variation.

Despite this rich complexity, the research over nearly 60 years has focused almost exclusively on the endpoints of the paradigm; that is, normative research has tried to identify fear stimuli, whereas the more recent fear-reduction research has tried to modify the overt avoidance behavior. Virtually all of the variables between, observable or inferred, have been left unexplored, leaving one with little understanding of fear processes in children.

Future research will do well to follow the literature's hints and look more closely at the unexplored areas identified in this review, such as the possible adaptive value of children's fears, fear-prevention strategies, cognitive self-control variables, and developmental factors. In short, we must recognize and test far more complex paradigms of the fear process. And finally, we clearly must correct our continued lack of information regarding severe levels of children's fear.

Cognitive Development in Retarded and Nonretarded Persons: Piagetian Tests of the Similar Sequence Hypothesis

John R. Weisz
University of North Carolina at Chapel Hill

Edward Zigler
Yale University

From the debate over developmental "universals" in Piagetian theory and the controversy between developmental and difference theories of mental retardation, an important hypothesis emerges—one that is testable via cognitive–developmental comparisons between retarded and nonretarded persons. This *similar sequence hypothesis* holds that retarded and nonretarded persons traverse the same stages of cognitive development in the same order, differing only in the rate at which they progress and in the ultimate developmental ceiling they attain. Current evidence relevant to this hypothesis is drawn from 3 longitudinal and 28 cross-sectional studies of developmental phenomena described by Piaget. The great preponderance of this evidence supports the hypothesis with respect to every subject group, with the possible exception of individuals suffering from pronounced electroencephalogram abnormalities. The quality of current evidence is critically evaluated, and procedures by which more precise tests of the hypothesis might be fashioned are proposed. Overall, the review illustrates that developmental research with atypical populations can be a potent tool in testing general developmental theory. Conversely, it illustrates the power of general developmental theory to enrich our understanding of atypical development.

In recent years two important theoretical issues have stimulated interest in Piagetian research with retarded and nonretarded populations. One is the question of whether developmental "universals" exist. Many psychologists regard the sequence of developmental stages described by Piaget (e.g., 1970) and elaborated by other cognitive–developmental theorists (e.g., Kohlberg, 1969) as one of psychology's few current candidates for universality (see Weisz, 1978). Piaget (1956, 1966) took a psychological universalist position, with qualifications, and Kohlberg (1969, 1971) argued strongly for the invariance of what he regarded as a cognitive–developmental sequence rooted in an inherent logic and in universal characteristics of both the nervous system and the environment.

Of course it is impossible to know that any given developmental phenomenon occurs everywhere without exception, since one can never test all possible exceptions (Popper, 1959). However, if one is not to let the claims of cognitive–developmental theorists go unchallenged, it is important to evaluate the extent to which *transcontextual validity* (see Weisz, 1978) has been demonstrated for the Piagetian account of development.

One approach to assessing such validity across experimental contexts is to examine developmental sequences across various cultures (Buck-Morss, 1975; Simpson, 1974). Another approach, of particular interest because of the cognitive emphasis of Piagetian theory, is to compare groups of children who differ markedly in measured intelligence, that is, groups of mentally retarded and nonretarded children. If children at very different IQ levels were to show identical Piagetian developmental sequences, then the transcon-

This review was supported by a New York State Human Ecology research grant to the first author and by National Institute of Child Health and Human Development Grant 5 POI HD 03008 to the second author. The authors are grateful to Thomas Achenbach and Sally Styfco for their thoughtful comments on a draft of the article.

Requests for reprints should be sent to John R. Weisz, Department of Psychology, University of North Carolina, Chapel Hill, North Carolina 27514.

textual validity of the Piagetian account of development would be substantially supported. If retarded and nonretarded children were to differ in their sequence of development, then universality could hardly be claimed for the Piagetian account.

A second theoretical issue that has sparked recent interest in comparative cognitive research is reflected in the ongoing debate between proponents of *developmental* and *difference* theories of mental retardation. The developmental position, set forth by Zigler (1969), is intended to apply to retarded individuals not suffering from organic impairment. Zigler has maintained that the retarded child passes through cognitive–developmental stages in the same order as the nonretarded child, with only two differences: The retarded child passes through the stages more slowly and attains a lower upper limit relative to the nonretarded child.[1]

A number of theorists hold what Zigler labeled the *general difference* position. One aspect of this position is the view that the cognitive development of retarded persons differs from that of nonretarded persons in ways that go beyond mere differences in rate and ceiling of development. Milgram (1973), for example, maintained that the cognitive levels, or stages, of retarded children differ from those of the nonretarded in that the former are more likely to contain traces of developmentally earlier levels and are more likely to show regression to those earlier levels. (For further discussion of the developmental position, the specific difference positions, and the rationale underlying them, see Weisz & Zigler, in press.)

This theoretical conflict has generated a new emphasis on comparative research into the processes (rather than the products) of learning and reasoning (Weisz, 1977; Weisz & Achenbach, 1975) and into processes of reasoning, as described in Piagetian theory (see Wilton & Boersma, 1974).

The growing interest in the pursuit of developmental universals, and the growing intensity of the developmental versus difference debate, have thus combined to lend theoretical force to research comparing the cognitive development of retarded and nonretarded persons along Piagetian lines. This body of research has grown rapidly within the past decade; it now appears to be substantial enough to serve as a resource in our efforts to answer the principal question raised by the universality issue and the developmental versus difference debate. This question can be stated in the form of a testable hypothesis.

Similar Sequence Hypothesis

An appropriate label seems to be the *similar sequence hypothesis*. The hypothesis holds that during development retarded and nonretarded persons traverse the same stages in precisely the same order and differ only in rate of development and in the ultimate ceiling they attain. To be precise, the developmental position (Zigler, 1969, 1971) generates this hypothesis only with respect to nonretarded and cultural–familial retarded persons (thus excluding, for example, brain-damaged and genetically impaired individuals).[2] In

---

[1] An additional postulate of the developmental position is that familial retarded and nonretarded persons who are equivalent in developmental level (often operationally defined as mental age) do not differ in the formed cognitive processes they employ in learning and reasoning. This particular proposition is not germane to the present review and consequently is not discussed here. However, Piagetian evidence bearing on this proposition is being reviewed (Weisz & Zigler, in press).

[2] The reasoning underlying this qualification bears brief explanation. The developmental position holds that mental retardation can be viewed as a developmental phenomenon most appropriately among persons whose retardation does not result from specific physiological defects. Such investigators as Benton (e.g., 1962), Cruikshank (e.g., 1967), and Reitan (e.g., 1973) have devoted many years to demonstrating idiosyncratic performance characteristics that distinguish brain-injured individuals from those with intact nervous systems. Furthermore, a number of studies employing the specific kinds of problem-solving tasks most often used in research on the developmental–difference controversy have revealed effects of organicity on retarded children's performance (Balla, Styfco, & Zigler, 1971; Balla & Zigler, 1964; Elkind, Koegler, Go, & Van Doorninck, 1965; Harter, Brown, & Zigler, 1971). In harmony with such findings, proponents of the developmental position have adhered to the two-group approach (see Zigler, 1969), whereby familial retarded individuals are distinguished from those suffering from organic impairment (including genetic anomalies such as Down's syndrome). There is some disagreement among investigators over the need for the two-group approach (Ellis, 1969; Milgram,

cognitive–developmental theory, however, the claims for the universality of the developmental sequence appear to be broader. Piaget (1956) held that "the *minimum* program for establishment of stages is the recognition of a distinct chronology, in the sense of a *constant order of succession*" (p. 13). According to Kohlberg (1969), the claim that there is an invariant order of cognitive stages rests upon an assumed invariance in certain features of the environment and of the nervous system and upon "a logical analysis of orderings inherent in given concepts" (p. 355). These inherent orderings are seen as logically essential and as independent of individual differences among people. Kohlberg continued, "The invariance of sequence in the development of a concept or category is not dependent upon a prepatterned unfolding of neural patterns; it must depend upon a logical analysis of the concept itself" (p. 355). Thus, the similar sequence hypothesis as advanced by cognitive–developmental theorists seems to predict a truly universal ordering of stages—an ordering that is the same for retarded children of all etiologies (including genetic impairment, brain injury, and other neurological anomaly) as it is for all nonretarded children. There is a conservative version of the similar sequence hypothesis that applies only to familial retarded and nonretarded persons and a liberal version that applies to all persons. In the present article we present evidence bearing on both versions.

In contrast with both these versions, Milgram (1973) has argued that the retarded child's cognitive stages differ from those of the nonretarded child. In contrast with the liberal version of the hypothesis, Rogers (1977) has described a rationale for (though she has not necessarily endorsed) the hypothesis that profoundly (and thus nonfamilial) retarded children have abnormal developmental patterns.

1973). Moreover, there is a strong Piagetian rationale for applying the similar sequence hypothesis to all persons, retarded or nonretarded, organically impaired or intact (see the remainder of the paragraph for details). In what follows we describe this rationale, and we go on to review evidence in a manner that bears directly on the conservative, two-group-oriented version of the hypothesis and on the more liberal version in which the similar sequence hypothesis is applied to all retarded groups regardless of etiology.

Material Excluded From the Present Review

The present article is an attempt to synthesize studies relating to the similar sequence hypothesis. In selecting studies to be reviewed, we excluded studies of reading per se and of language development per se. Although both areas can be viewed from the perspective of Piagetian theory, neither is central to the theory; furthermore, the research in both areas is now so voluminous as to warrant separate review. We also excluded studies designed to accelerate cognitive development, since it is not the purpose of this article to determine whether retarded or nonretarded children can be trained more readily.

The studies we do include in this review vary widely in their sampling procedures, their experimental methodology, and their approaches to data analysis and reporting. Consequently, the studies differ in their level of importance vis-à-vis the hypothesis of particular interest here. For this reason, we reserve the right to vary the level of detail in which we describe the studies and give relatively greater space to those that seem to afford the clearest tests of the hypothesis.

Tests of the Similar Sequence Hypothesis

Cross-Sectional and Order-of-Difficulty Evidence

One approach to testing the similar sequence hypothesis is to assess groups of mentally retarded children at more than one developmental level with respect to their performance on various Piagetian tasks. If the direction of the difference in performance from one developmental level to another is the same for the retarded as for the nonretarded, or if the direction is consistent with the developmental sequence posited by cognitive–developmental theory, then the similar sequence hypothesis is supported. A second general approach to testing the similar sequence hypothesis is to rely less upon the developmental levels of the groups sampled than upon the relative-difficulty levels of the various tasks or behavioral items being employed. Perhaps the simplest, but also the least informative, of the variants of this approach

is to rank order the items with respect to the number of subjects who pass each one; if this rank ordering of a retarded sample matches either the rank ordering of a nonretarded sample or the developmental sequence posited by cognitive–developmental theory, then the similar sequence hypothesis is supported, albeit modestly. A more informative type of order-of-difficulty evidence is the type that employs scaling procedures, allowing one to determine, for example, how many of the children who grasp Concept A also grasp Concept B and vice versa. Such evidence, when combined with Guttman-type (e.g., Guttman, 1950) scalogram analyses, can provide a relatively strong test of the similar sequence hypothesis. The studies reviewed in this section all employed some type of cross-sectional evidence, order-of-difficulty evidence, or a combination of the two.

Development in the sensorimotor period. Early evidence bearing on the similar sequence hypothesis was provided by the research of Woodward (1959, 1961, 1962, 1963). The first of her studies (1959) focused primarily on a group of 65 institutionalized children and adolescents with a chronological age (CA) range of 7–16 years who were so profoundly retarded that they failed to attain a basal age of 2 years on the Terman-Merrill scale. Although the author maintained that this sample excluded cases involving motor or sensory disability, the cases involved a diversity of medical problems (e.g., 19 subjects were epileptic), and 38 of the children were "emotionally unstable." Woodward used three means of assessing the sensorimotor stages of this heterogeneous group. First, she observed their spontaneous mannerisms and their manipulation of toys presented individually and in a standardized order. Second, each subject was presented with three pairs of tasks, each pair tapping one of Piaget's (1953, 1955) last three sensorimotor stages (there are six stages in all). Third, Woodward presented each child with a series of object concept tasks in which a piece of candy or a toy was first used to attract the subject's attention and was then withdrawn and concealed to varying degrees.

All but the object concept tasks were analyzed in a way that sheds light on the similar sequence hypothesis. Each task was classified with respect to the Piagetian sensorimotor stage it was designed to represent; then the tasks were ranked ordered with respect to the percentage of subjects passing each. The difficulty level rankings of these 11 items were identical to the Piagetian stage level order, with one exception: A task involving coordination of vision and hearing (Sensorimotor Stage 2) proved to be slightly more difficult than a task involving manipulation of objects (Stage 3); 53 subjects passed the manipulation task, and only 49 passed the coordination task. Furthermore, when the possibly insensitive coordination task was removed from the analyses, 59 of the 65 children passed all of the items at stages below their highest stage level response. Given the extreme diversity of this sample, the high incidence of emotional instability, and the apparent tendency of many not to show responses of which they were actually capable (e.g., some delayed for a half hour before grasping an object placed before them), these data lend surprisingly strong support to the similar sequence hypothesis.

Recently, Rogers (1977) undertook an investigation similar to that of Woodward in several respects. The subjects, 40 profoundly retarded children ranging in age from 8–14 years, with IQs below 20, were given a series of Piagetian tasks. By means of these tasks, each child's performance was classified into Sensorimotor Stage 3, 4, 5, or 6 in each of four conceptual domains: object permanence (tasks involving searches for a hidden object), spatiality (tasks involving visual anticipation and rotation of objects), causality (tasks involving the use of physical prompts and tools, the removal of obstacles, and inference as to the cause of a jingling sound inside a box), and imitation (tasks involving the reproduction of both self-initiated and experimenter-initiated movements and sounds). Performance within each of the four domains was analyzed using scaling techniques, and Guttman's (1950) coefficient of reproducibility and Green's (1956) index of scalability were calculated for each scale. The object permanence and imitation tasks formed highly reproducible scales in the orders hypothesized by Piaget (1955, 1962, 1972). Causality tasks also

formed a highly reproducible scale, although the item order differed from the predicted sequence in one respect: One Stage 6 item preceded one Stage 5 item. The author attributed this irregularity to a poor choice of Stage 6 task (i.e., opening a box to obtain a bell when box opening has just been demonstrated to the subject), "since the task used might have been accomplished using imitation rather than problem-solving skills" (Rogers, 1977; pp. 841–842). Finally, the individual spatiality tasks did not all form highly reproducible scales, but when the tasks within each stage were combined (and subjects were credited with a stage level for passing one or more of the tasks from that level), the stages did form a highly reproducible scale. Rogers concluded convincingly that her findings support "the invariant sequentiality of sensorimotor stages" (p. 841).

The preoperational–concrete operational transition—the Inhelder study of conservation. One of the earliest studies bearing on the similar sequence hypothesis was carried out by Piaget's associate, Barbel Inhelder, in the early 1940s. This study, now published in English (Inhelder, 1943/1968), involved the assessment of conservation of substance, weight, and volume in 159 persons who had been labeled mentally retarded by Swiss education officials. The sample was extremely heterogeneous (see Jordan, 1976). Ages ranged from 7½–52 years, IQs ranged from 35–104, institutionalized and noninstitutionalized persons were included, and the range of etiologies and physical maladies included such diverse states as "defective environment," rickets, hearing defect, "abandoned," and schizophrenia. The procedure involved semistructured clinical interviews with each subject. Since the procedure was not perfectly standardized and little in the way of formal data analysis was presented, it is difficult to evaluate Inhelder's conclusions, including her references to "oscillations" in the reasoning of retarded subjects, discussed later in this article. However, in Piaget's (1968) description of the Inhelder study, he explained that in the entire sample,

> not one [individual] understood the conservation of weight without having the conservation of substance, nor the conservation of volume without both weight and substance, while the conservation of substance *was* found without the other two, and the conservation of weight was found without the conservation of volume. (p. 11)

Given the marked heterogeneity of the sample, such uniform support for the similar sequence hypothesis is noteworthy.

Other studies of conservation and related concepts using retarded samples only. Studies of conservation and related concepts done since the Inhelder investigation have a bearing on the similar sequence hypothesis, despite the fact that they only sampled retarded subjects. Klauss and Green (1972) assessed conservation of number and volume in 27 trainable mentally retarded subjects ranging in age from 13–19 years and in IQ from 29–57. These investigators found that volume conservation presented greater difficulty than did number conservation, a finding consistent with the pattern apparent in the nonretarded. Marchi (1971) tested conservation of mass, weight, and volume in 106 educable mentally retarded children. Difficulty level evidence suggested that contrary to Marchi's prediction, the retarded "follow a similar sequence in the acquisition of mass, weight, and volume as postulated for normals" (p. 6442).

Roodin, Sullivan, and Rybash (1976) assessed qualitative identity, quantitative identity, and equivalence conservation (see Elkind, 1967) in 60 institutionalized retarded children averaging 13 years of age and about 47 in IQ. Dyed water was poured from a standard 100 ml beaker; to test qualitative identity, subjects were asked, "Is the water in this glass (comparison) the *same* water that was in that glass (empty standard)?" To assess quantitative identity, subjects were asked, "Is there *as much* water in this glass (comparison) as there was in that glass (empty standard)?" To assess equivalence conservation, two standard beakers were filled with equal levels of water, and the contents of one were then poured into a comparison beaker; the experimenter then asked, "Is there *as much* water in this glass (standard) as there is in this glass (comparison)?" Previous reasearch (e.g., Papalia & Hooper, 1971) with nonretarded children had suggested that the developmental order for the attainment of these three concepts would be qualitative identity, quantitative identity,

and equivalence conservation. In the Roodin et al. study, analyses of the number of conservers on each task indicated a parallel order of difficulty.

In a similar study also employing 60 institutionalized retarded children (age range of approximately 10–16 years and average IQ of approximately 57), McManis (1969c) investigated identity and equivalence conservation with three types of material (Styrofoam balls, clay, and water). Like Roodin et al. (1976), McManis found evidence that the developmental sequence of his retarded subjects replicated that of nonretarded children. The notion that identity conservation must precede equivalence conservation was supported by the finding that no subject who failed to achieve identity conservation showed equivalence conservation, whereas 13%–18% of the subjects (precise percentage depending on the particular task used) displayed identity conservation without equivalence conservation.

Three studies that examined conservation of number, and number concepts generally, in mentally retarded groups yielded similar findings, despite some differences in methodology. Woodward (1961) investigated numerical concepts of 94 institutionalized individuals (50 adults with average CA of 19 years and 44 children and adolescents with average CA of 12 years) ranging in IQ from 25–73. Tests given to the subjects included assessments of their understanding of (a) one-to-one correspondence and equivalence of corresponding sets, (b) ways of equalizing unequal groups, (c) seriation, and (d) conservation of continuous quantity (water and sand). Performance was scored as indicative of one of two preoperational stages or of concrete operational thinking. When the stage level assignments were plotted as a function of the IQs (and thus roughly of the mental ages or MAs) of the adult subjects sampled, the table reflected precisely what would be expected from the application of Piaget's stage scheme to nonretarded individuals.

In the second of the three studies, Mannix (1960) administered eight of Piaget's (1952) number concept tasks to 48 "educationally subnormal" individuals ranging in MA from 5–9 years. The tasks included two tests of additive composition, one test of coordination of equivalence relations, two tests of judgment of correspondence between sets of items, and two conservation tasks (continuous and discontinuous quantities). Responses to these tests were classified into Piagetian stage levels, a scalogram was constructed, and the coefficient of reproducibility was .94. Mannix's brief report gave little information as to the precise nature of the scale types; but apparently the scalogram was consistent with Piaget's stage theory, because the author concluded that educationally subnormal children "pass through the three stages of development described by Piaget" (Mannix, 1960, p. 181).

The third of these studies on number concepts was conducted with 20 institutionalized mentally retarded persons in New Zealand (CA range of 8–17 years; IQs of 29–65). Singh and Stott (1975) presented these subjects with a series of number conservation tasks designed to classify them with respect to three Piagetian number stages: Stage 1—child fails to attend to relevant cues and fails to conserve; Stage 2—child selectively attends to only certain relevant cues, can match perceptually, but cannot conserve; Stage 3—child conserves, showing understanding of invariance of properties despite transformation in appearance. Data bearing on the similar sequence hypothesis are not reported in detail, but the authors' conclusion is quite clear: "Retarded children apparently develop sequentially in the same order as normals but at a slower rate and at a later CA" (Singh & Stott, 1975, p. 220).

One other study that used only a retarded sample deserves mention both because of its scope and because of an important issue it raises. In this study, Lister (1972) assessed six types of conservation among 115 educationally subnormal pupils in Great Britain. The subjects were aged 8–16 years, and their IQs ranged from 47–81. Both difficulty level rankings and a scaling procedure strongly suggested the following developmental sequence in the emergence of these types of conservation: number, substance, length, weight, volume, and area. Although no scalogram statistics were calculated, only 6 of the 115 subjects showed a scalogram response pattern inconsistent with the preceding order.

Lister noted that the order with respect to substance, weight, and volume was consistent with previous Piagetian research, whereas the suggested order of the remaining attributes differed from at least some previous findings with nonretarded subjects. Her own interpretation of the discrepancies was that they resulted from experiment-to-experiment variations in the specifics of the problems used to assess the various types of conservation. This is a very real possibility, and it is one reason why tests of the similar sequence hypothesis that expose retarded and nonretarded subjects to the same experimental procedures must be regarded as stronger evidence than experiments that test only retarded children and compare the findings with those of different experiments. We now turn to six studies of the former type.

Studies of conservation and related concepts employing both retarded and nonretarded subjects. Four of the experiments in which the performance of retarded and nonretarded subjects was directly compared were conducted by McManis (1969b, 1969d, 1969e, 1970). In one of these, 90 institutionalized retarded subjects (IQs of 47–73) and 90 nonretarded elementary school children (IQs of 85–115) were tested for conservation of mass, weight, and volume of clay, using Piaget and Inhelder's (1941) "sausage" technique. About half the retarded subjects were organically impaired. Analyses of the mean scores for the conservation tasks indicated that conservation of mass was easiest and conservation of volume most difficult for both the retarded and the nonretarded group, providing some support for the notion that the order of emergence of these types of conservation in groups of both average and below-average IQ is as follows: mass, weight, then volume.

In another article McManis (1969e) reported his assessment of conservation and transitivity of weight (clay) and length (sticks) in what appears to be the same sample used in his 1969d experiment. The study was designed to test the hypothesis, derived from Kooistra (1964), that for any given property (e.g., weight) conservation will appear developmentally earlier than transitivity. The results supported this hypothesis for both weight and length in retarded and nonretarded subjects. McManis (1970) then explored the relations among conservation, seriation, and transitivity (of length) within groups of 80 institutionalized mentally retarded persons (IQs of 46–72) and 80 nonretarded elementary school children (IQs of 85–116). Among both retarded and nonretarded children who showed discrepant performance on the conservation and seriation tasks, nearly all showed conservation without seriation. Among both retarded and nonretarded children who showed discrepant performance on the seriation and transitivity tasks, nearly all showed seriation without transitivity. These findings indicate that seriation falls developmentally between conservation and transitivity (at least with respect to the property of length, as measured in this experiment) for both retarded and nonretarded persons.

In a fourth article based on the same sample used in two of the preceding studies (McManis, 1969d, 1969e), McManis (1969b) tested Piaget's (1952) view that there are three hierarchically ordered stages in the development of quantitative comparison processes. In the first stage, children are said to consider only uncoordinated perceptual relations of gross qualitative equality or difference; in the second stage, intensive quantity, children are said to compare quantities by seriating them along more than one dimension (e.g., width and height) simultaneously; in the third stage, extensive quantities, children are said to be capable of overruling apparent differences between two equal quantities by imposing equal units of measurement upon them. McManis tested his young subjects' performance of these three types of comparison, using sticks, colored water, and beads. The analysis of scores on these tasks indicated that for both the retarded and the nonretarded group, gross comparisons were the simplest (they were passed by nearly all subjects in both groups) and extensive comparisons were the most difficult. These findings are consistent with the view that for children at both IQ levels the developmental order is as follows: gross, intensive, and extensive quantity (the order posited by Piaget). One other study (McManis, 1969a) should be mentioned in this connection. McManis's tests of quantity com-

parison were given to 140 institutionalized mentally retarded persons, who were divided into equal groups representing different IQ levels (IQs of 30–49 and of 50–69). The procedure and analyses were similar to those employed in the preceding study (McManis, 1969b). The results indicated, as in the preceding experiment, that comparison of gross quantities was easiest and comparison of extensive quantities was most difficult, regardless of the IQ level of the subjects.

Three other comparative studies were designed to address the problem of order of events across the types of conservation. Gruen and Vore (1972) assessed conservation of number (poker ships), continuous quantity (water), and weight (clay rolled into various shapes) in familial retarded (IQs of 55–80) and nonretarded (IQs of 90–120) public school pupils. Both retarded and nonretarded groups were divided into three subgroups of MA: 5, 7, and 9 years. Evidence on developmental ordering was in the form of mean scores for the three types of conservation, analyzed within each MA level. In one set of analyses, conservation judgments alone (i.e., disregarding the subjects' verbal explanations) constituted the dependent variable. With this criterion, performance of nearly all subjects at MA 9 was correct; for the other two MA levels, both retarded and nonretarded subjects tended to score significantly better on the number task than on the quantity or weight tasks. For nonretarded children at MA 7, however, the differences were not significant. The quantity and weight tasks did not differ significantly in difficulty for retarded and nonretarded children.

In a second set of analyses by Gruen and Vore, the dependent measure was conservation judgment in combination with the subject's explanation for that judgment. Using this criterion, there was no significant task effect at the MA 5 level. At the MA 7 level both retarded and nonretarded subjects did somewhat better at the number task than at the quantity and weight tasks, but the differences were only significant for the retarded subjects. At the MA 9 level both retarded and nonretarded subjects scored significantly higher on the number than on the weight task and significantly higher on the quantity than on the weight task. Thus, although order-of-difficulty patterns were similar for retarded and nonretarded subjects, with use of judgments alone and judgments plus explanations, task differences tended to be statistically significant among the retarded more often than among the nonretarded. In attempting to account for this trend, Gruen and Vore (1972) made an interesting point:

> McManis (1969[e]) has suggested that there is a transitional period (MAs of 7–10) in which the various concrete operations are obtained and that retarded children progress through this period more slowly than do normal children. If this is true, it would be expected that the performance of normal children on various conservation tasks would vary less from task to task than that of retarded children. This also suggests that retarded children may be ideal subjects for investigating the transition process from preoperational to concrete-operational thinking. (p. 156)

We conclude this section of the review by discussing two conservation studies by Achenbach. Building on the work of Charlesworth (1969) and Mermelstein and Shulman (1967), Achenbach (1973) inferred children's identity concepts with respect to color, number, length, and continuous quantity from their surprise reactions to contrived changes in those properties. For example, to test number identity concepts two toy Indians were placed in a box, and when the bottom was opened three Indians dropped out. Among nonretarded subjects (M IQ = 116), there were significantly more frequent surprise reactions to a change in color than to changes in the three quantitative properties, a finding consistent with Piaget's view (see Piaget & Voyat, 1968) that children develop identity concepts for qualitative properties such as color prior to the emergence of identity concepts for quantitative properties such as number, length, and continuous quantity. Surprise reactions to change in color and number were virtually identical in 45 familial and 16 Down syndrome retarded subjects (M IQ = 47). The frequencies of surprise reactions to changes of the three different quantitative properties for both retarded and nonretarded subjects are consistent with the findings of others (including Gruen & Vore, 1972) that successful performance on conventional length and number conservation tasks is simpler than, and thus presumably developmentally prior to,

success on conventional continuous quantity tasks. Thus, once again we see fairly strong support for the view that the sequence of developmental events for the retarded child is similar to that for the nonretarded child.

A different type of similarity is illustrated by Achenbach's (1969) study of nonretarded public school children (IQs of 94–168) and nonorganically impaired retarded children (IQs of 31–78) from public schools and institutions. He assessed children's conservation concepts with respect to length, area, and volume[3] (employing 4 tasks for each of the three properties) by using optical illusions to create discrepancies between the actual and apparent sizes of various stimuli. To test conservation of length, for example, the experimenter presented each child with a barbell illusion in which a small metal rod that fit into a groove that just touched the inner edges of two circles was placed into another groove that passed through two circles and touched their outer edges. The effect was to make the rod appear longer in the second position than in the first. Subjects were then asked whether the rod would fit into the original groove. An important feature of the study, for our purposes, is that the 12 tasks were designed to be free of intellectual demands in the areas of additivity, numeration, conservation of equivalence, or complex verbal expression—dimensions along which more traditional conservation tasks often vary. This made it possible to test the contention of Braine and Shanks (1965a, 1965b) that the attainment of conservation with respect to the various properties would be parallel if the performance criteria used were standard across the types of conservation. Consistent with the Braine–Shanks view, Achenbach (1969) found a "total absence of evidence for a horizontal *décalage*" (p. 677) in the three types of conservation, for both the retarded group and the nonretarded group. In both groups, there were neither consistent nor significant differences in success rates for length, area, and volume tasks. This finding, together with the reasoning of Braine and Shanks, suggests that some of the order-of-difficulty and scalogram-type evidence reviewed in the preceding paragraphs may be more indicative of differences in the specific requirements of the contrived tasks employed than of actual differences in the order of emergence of the various types of conservation.

Concepts of time. A number of studies have addressed the similar sequence hypothesis in content areas other than conservation. In one study on the concept of time, Lovell and Slater (1960) interviewed 50 educationally subnormal children (IQs not reported) aged 8, 9, 10, 11, and 15 years and 50 "average to above average" children aged 5–9 years. The interview included tasks (some were Piaget's) designed to measure concepts of simultaneity and equality of synchronous intervals (e.g., asking the child to judge whether two dolls traveling at different rates but starting and stopping at the same time actually traveled for the same amount of time). There were also tasks involving chronological ordering of events and children's concepts of age and interior time. Little in the way of statistical analysis was reported, but nonetheless, Lovell and Slater concluded that the understanding of these five concepts of time follows roughly the same sequence in retarded as in normal children, although the stages in understanding are reached some years later by retarded children.

Concepts of space. Two studies that included a retarded sample were specifically concerned with spatial concepts. In one of these, Houssiadas and Brown (1967) sampled 40 institutionalized, mentally retarded Australians (M IQ = 55) who showed no evidence of mongolism or other specific defects and who ranged in age from 8–15 years. These subjects were presented with two perspective-taking tasks (one pictorial and one using manipulation of actual objects) in which they were asked to identify their own perspective on a perceptual array as well as the perspective of another person seated at a different position. Although no statistical analyses were reported, the pattern of passes and failures on the different items was consistent with the view that retarded individuals pass through the stages identified by Piaget; that is, first there is difficulty in identifying one's own perspective

[3] The volume conservation task used by Achenbach (1969) actually tapped what Piaget (has) called conservation of *continuous quantity*.

and that of another, second there is only difficulty in identifying how a perceptual array might look from another position, and third the individual is able to "coordinate perspectives," identifying not only his own perspective but that of another person as well. Summing up, Houssiadas and Brown (1967) concluded, "It is clear that the pattern of predominant responses follows the same sequence suggested by Piaget, whose data were derived from normal children" (p. 213).

In a more fine-grained analysis of spatial concepts, Woodward (1962) tested the same institutionalized retarded group of 50 adults and 44 children used in the study of number concepts described earlier (Woodward, 1961). In this sample, 50% of the adults and 61% of the children showed some type of organic impairment. The spatial tasks included measures of the ability to reproduce a spatial order under varying degrees of transformation (e.g., reproducing a circular array of beads on a horizontal rod). Using a similar procedure with nonretarded children, Piaget and Inhelder (1956) identified seven stages through which their children passed as they improved on the tasks. Woodward (1962) constructed a table of scale types to assess the comparability of her results with those of Piaget and Inhelder. Although no scalogram statistics were calculated, the great majority of Woodward's subjects fit scale types consistent with the developmental sequence posited by the Genevans.

A second task employed by Woodward involved drawing copies of 21 geometric figures used by Piaget and Inhelder. The compatibility of subjects' scores on these tasks with a four-stage sequence advanced by Piaget and Inhelder (1956) was demonstrated by the fact that "subjects classified by the features of a given stage showed the features of the lower stages in most cases" (Woodward, 1962, p. 31). However, once again no scalogram statistics were reported, and 5 of the 14 performance criteria by which stage assignments were made were outside the appropriate difficulty level for at least some of the subjects. The third task employed by Woodward was a "reference points" problem in which adult subjects only were presented with drawings of a bottle tilted at various angles and said to be about one-fourth full of water. The subjects' task was to pencil in the portion of the bottle occupied by the water. The performance data presented for this task were extremely sketchy, but Woodward indicated that the order of difficulty of the tasks was the same as that found by Piaget and Inhelder. In her overview of her findings bearing on what we have called the similar sequence hypothesis, Woodward (1962) concluded that for her retarded subjects, "The sequence suggested by Piaget and Inhelder [for nonretarded children] was confirmed for all three spatial concepts that were investigated" (p. 35).

Relative thinking. In investigating the "logic of relations" in children, Piaget (1928) used a "brothers and sisters" problem and a "right and left" problem. In the former problem, children's understanding of the relation between being and having a sibling was explored by asking such questions as "George has three brothers, Paul, Henry, and Charles. How many brothers has Paul? How many brothers are there in this family?" In the right and left problem, children were instructed, "Show me your right hand, your left. Show me my right hand, my left" Lane and Kinder (1939) used these two Piagetian problems with 50 institutionalized retarded individuals of unspecified etiology who were grouped, for purposes of data analysis, into four different IQ levels: 38, 51, 64, and 77. Instead of scalogram statistics, relative levels of the questions were reported for each IQ group. These data indicated that the rank ordering of difficulty for the 11 questions was similar across the different IQ levels—a parallelism consistent with the similar sequence hypothesis.

Moral judgment. Abel (1941) investigated moral judgment in 74 institutionalized "subnormal adolescent white girls" (aged 15–21 years; IQs unspecified). Subjects were questioned about seven brief stories concerning immanent punishment (the inevitability of punishment following a misdeed), retributive justice (punishment orientation, particularly of the "eye for an eye" variety), and judgments of the gravity of a misdeed (using information on consequences of the deed and intent of the transgressor). Mirroring previous findings with

nonretarded individuals (Lerner, 1937, 1938), Abel's findings were that with increasing maturity (defined in terms of MA) subjects gave nonsignificantly greater weight to intent and less weight to consequences in judging the gravity of a misdeed and were significantly less likely to consistently advocate retributive punishment. Unlike the nonretarded persons in at least some research, Abel's more mature subjects (MAs of 9–11 years) did not show any less pronounced a belief in immanent punishment than did her less mature subjects (MAs of 6–8 years). In fact, about 82% of both groups showed such a belief, which Abel (1941) attributed to the "constraining" institutional environment "that controls the girls with threats of immanent punishment" (p. 386). Except for this one anomaly, the Abel data are consistent with the similar sequence hypothesis.

Studies of multiple concepts. We conclude this section on cross-sectional research with a discussion of studies that have assessed concepts in more than one conceptual domain. DeVries (1970, 1973a, 1973b, 1974) assessed a variety of Piagetian concepts in bright (M IQ $\approx$ 130), average (M IQ $\approx$ 105), and retarded (M IQ $\approx$ 72); etiologies not reported) children, all enrolled in public schools. The tasks included the brothers and sisters and right and left problems described earlier; tests of generic and sex identity and of conservation of mass, number, length, and liquid; interviews on magic and dream concepts; object sorting and class inclusion problems; and a guessing game ("Which hand has the penny?") designed to reveal the level of children's role-taking skills. Of all the tasks used, data from the guessing game task were presented in the most complete manner (see DeVries, 1970). Using an independent sample of 64 high-IQ children, DeVries (1970) classified behavior on the guessing game with respect to 10 characteristics (e.g., does not always hide penny in the same hand). These characteristics formed a highly reproducible Guttman-type scale with a reproducibility of .95 and an index of consistency of .66. The scale was then used with the bright, average, and retarded samples and checked against Kohlberg's (1969) criteria for developmental sequentiality, namely, (a) mean scale scores should increase with age, (b) success on each individual scale item should increase with age, and (c) the sequence of items should be justifiable with a logical rationale based on Piagetian theory. DeVries (1973b) maintained that her scale met the third criterion, and her data (DeVries, 1970) indicate that the first two criteria were met within the bright, average, and retarded groups separately. Similar analyses were carried out with respect to the other 14 Piagetian tasks, with a Guttman scale constructed for each. Within the average and retarded groups each scale met Green's (1956) criterion of an index of consistency greater than .50, and the lowest coefficient of reproducibility was .94 (DeVries, Note 1). DeVries (1973b) indicated that all of the Kohlberg criteria for sequentiality "were applied to each ability group (i.e., bright, average, and retarded subjects) separately, and the order of scale items was the same for each ability group on all tasks" (p. 3).

Stearns and Borkowski (1969) investigated conservation of continuous quantity (water) and discontinuous quantity (blocks and marbles) as well as horizontal–vertical space perception in institutionalized retarded individuals (IQs unspecified) ranging in age from $7\frac{1}{2}$–27 years. Consistent with Piaget's (e.g., 1964) view (and supporting findings; see Elkind, 1961) that conservation of continuous quantity is more difficult and emerges developmentally later than conservation of discontinuous quantity, Stearns and Borkowski found performance on their test of the former concept to be significantly poorer than performance on their two tests of the latter concept. Scores were also highly similar for the tests of horizontal and vertical frames of reference; this finding is consistent with Piaget's (see Piaget & Inhelder, 1956) view that concepts of the vertical and of the horizontal are acquired at the same time.

Finally, we turn to two studies by Lovell and his colleagues (Lovell, Healey, & Rowland, 1962; Lovell, Mitchell, & Everett, 1962). The studies reported few relevant statistical analyses, but the diversity of concepts examined makes them worthy of brief attention. In the Lovell, Mitchell, and Everett study, groups of nonretarded and educationally subnormal individuals (no IQs reported)

were divided into separate age groups. The skills investigated included additive and multiplicative classification (of objects and pictures differing in multiple dimensions), seriation, multiplication of asymmetrical transitive relations, hierarchical classification, class inclusion, and visual and tactile classification. For all tasks the tabled data indicated a general improvement in performance with increasing age level for both normal and subnormal groups (no significance tests reported).

In the study by Lovell, Healey, and Rowland, the subjects were again groups of nonretarded and educationally subnormal persons from special schools (IQs unreported) who were divided into separate age groups. The groups were presented with 12 of the tasks used by Piaget, Inhelder, and Szeminska (1960) to study the child's geometric concepts. Within normal and subnormal groups separately, correlation coefficients were calculated that related Piagetian stage levels on the 12 tasks to subjects' age levels. Of the 24 coefficients, 23 were significant at the .01 level. In both Lovell et al. studies, the details of subject selection, experimental procedure, and statistical analyses are so skimpy that the findings must be regarded as only suggestive. Nonetheless, although they are not by any means definitive, the data are in harmony with the similar sequence hypothesis.

Summary of the Cross-Sectional and Order-of-Difficulty Evidence on the Similar Sequence Hypothesis

Thus far we have reviewed 28 studies in which cross-sectional and order-of-difficulty evidence is reported in ways that have some bearing on the similar sequence hypothesis. The degree of retardation involved in the samples ranged from profound to mild; the retarded persons sampled ranged in age from childhood to adulthood, were both institutionalized and noninstitutionalized, and included both cultural–familial cases and individuals with diverse organic and emotional disorders. The nonretarded contrast groups, when employed, ranged from slightly below average to extremely high in IQ. The studies reported also varied widely in their experimental methodology and in their methods of data analysis. Despite this great diversity in methodology and in sample characteristics, the data reviewed show rather consistent support for the similar sequence hypothesis, both in its conservative form, which applies only to nonretarded and familial retarded persons (Zigler, 1969), and in its broader form, in which universality of developmental sequence is held to be independent of individual subject characteristics such as organic impairment (see Kohlberg, 1969).

There were very few exceptions to this generalization: (a) Woodward (1959) found that among her profoundly retarded subjects 1 sensorimotor task out of 11 proved to be slightly more difficult than another task that Piaget designated as being one sensorimotor stage higher. (b) Among Rogers's (1977) profoundly retarded subjects, a causality task designed to be at Stage 6 proved to be easier than one of the tasks at Stage 5, whereas individual spatiality tasks within each stage had to be combined to yield a highly reproducible scale. (c) In Achenbach's (1973) familial and Down's syndrome retarded sample, surprise reactions indicative of color and number identity occurred with equal frequency, whereas in his nonretarded sample, color surprise was significantly more frequent than number surprise. (d) Abel (1941) found no significant decline with increasing MA in belief in immanent punishment in her institutionalized female retarded sample, a finding that differs from some earlier research with nonretarded children.

These four instances of no support for the similar sequence hypothesis are exceedingly minor. They may have resulted, as the authors of these studies generally suggested from idiosyncratic (or misinterpreted) properties of the tasks selected or from other measurement errors, and in some cases (e.g., Abel, 1941) they may reflect the suppressive influence of an idiosyncratic environment that merely delays the shift from one level of reasoning to another. Furthermore, in each of the four studies, the findings of no support were outnumbered by findings supporting the similar sequence hypothesis.

While noting the strong level of support that the reviewed evidence has yielded for the similar sequence hypothesis, we must also note that such cross-sectional and level-of-

difficulty evidence, even at its best, can support only indirect inference regarding the actual process of development. Considerably more direct and potent inference is possible when an investigator observes the same individuals at more than one point during the course of development, that is, in longitudinal fashion. Such research is often expensive and complex, and consequently it is relatively rare, particularly with mentally retarded persons. However, three longitudinal studies have some bearing on the similar sequence hypothesis. We now turn to these.

Longitudinal Evidence

Development in the sensorimotor period. One longitudinal investigation was designed by Wohlhueter and Sindberg (1975) as an extension of Woodward's (1959) cross-sectional study of sensorimotor development in profoundly retarded persons (described earlier in this article). These investigators conducted monthly assessments of institutionalized 1–6-year-old profoundly, severely, and moderately retarded children (no IQs reported). The Piagetian object concept tasks used by Décarie (1965) were employed for 1 to $1\frac{1}{2}$ years or until a child performed at the highest of the 10 substage levels for 2 consecutive monthly sessions. Of the principal sample of 49 children, 20 had progressed to the highest substage level by the end of the study; of the remaining 29, 10 showed a generally monotonic increase, and 9 seemed to be at a plateau, with object concept levels the same for most of the 12 or more sessions. Thus, 39 of the 49 subjects showed patterns harmonious with the pattern of object concept stages posited by Piaget (1955) and found by subsequent investigators using nonretarded samples. For the remaining 10 subjects, however, there was a variable developmental pattern in which substage levels appeared to rise and fall from session to session, ranging over as many as 3 or 4 substages during the 12 or more sessions.

In an effort to determine what characteristics might distinguish this group of atypical subjects, Wohlhueter and Sindberg, (1975) examined medical histories and clinical findings for their sample; the distinguishing feature of the variable group was that the majority of subjects "were found to have EEG abnormalities, especially dysrhythmias or a history of seizures" (p. 516). This finding raises at least two possible interpretations with respect to the variable developmental pattern: (a) that individuals with brain anomalies associated with electroencephalogram (EEG) abnormalities may show atypical sequences of development with respect to the object concept and (b) that behavioral and attentional abnormalities in individuals with anomalous EEG patterns make accurate assessment of object concept substages difficult.

One other unusual pattern was noted by the investigators, namely, some children seemed to bypass or skip over some of the substages. This apparent skipping phenomenon has been noted in research with nonretarded children as well (see Uzgiris, Note 2). Although this is an interesting phenomenon, it is difficult to know how often skipped substages may actually have been traversed by the children in the intervals between experimental sessions. Furthermore, both the skipping phenomenon and the variability phenomenon might be better understood if we were able to rule out specific method effects, as could have been done if a nonretarded sample had been included in this study for comparative purposes. Nonetheless, the Wohlhueter–Sindberg investigation at least raises significant questions about the validity of the similar sequence hypothesis with respect to certain substages in the development of the object concept.

A longitudinal study reported by Cicchetti and Sroufe (1976), however, yields strong support for the similar sequence hypothesis within the sensorimotor period. The study focused on the relation between cognitive and affective development in home-reared Down's syndrome infants during the period from 4–18 months of age. Sroufe and his colleagues (e.g., Sroufe & Wunsch, 1972) earlier demonstrated that among normal infants there is a developmental progression from mirth response to auditory and tactile stimulation that is physically intense or vigorous (e.g., tickling the baby's chin or saying "Boom!") to mirth responses to social and visual stimulation that is progressively more subtle and complex (e.g., the sight of mother sucking on baby's bottle). At monthly intervals the infants sampled by Cicchetti and Sroufe were pre-

sented with 15 auditory and tactile items of the intense or vigorous type and 15 social and visual items of the more subtle and complex type. As in the earlier research with normal infants, the Down's syndrome infants laughed earliest in response to the auditory and tactile items and latest in response to "the more cognitively complicated social and visual items" (Cicchetti & Sroufe, 1976, p. 923). The responses of the Down's infants, of course, came months later (in CA) than did the corresponding responses of normal infants. Smile responses, a more sensitive index of positive affect in the Down's syndrome sample, showed the same pattern and revealed even more clearly than laughter responses the developmental decline in positive affect aroused by simpler auditory and tactile items as the infants matured beyond 13 months. This inverted-U-shaped developmental pattern also resembles earlier findings with normal infants. In stressing the similarity of their findings with Down's infants to those with normal infants, Cicchetti and Sroufe (1976) pointed out that the laughter items were similarly ordered for both groups, "category by category and, in the main, item by item" (p. 923). Finally, to assess the merits of their claim that the affective responses they measured were closely related to cognitive development, Cicchetti and Sroufe calculated correlations of indices of affective expression (e.g., earliest laugh, total amount of smiling to all items, etc.) with the Bayley mental and motors scales and the Uzgiris–Hunt object permanence and operational causality scales. All 44 correlations were statistically significant.

Therefore, the Cicchetti–Sroufe investigation, unlike the Wohlhueter–Sindberg study, provides uniform support for the liberal version of the similar sequence hypothesis in which the hypothesis is applied to all retarded children regardless of etiology. The Cicchetti–Sroufe research deserves special attention because of its unusually careful methology and its emphasis on the integrity of the developing infant. The research demonstrates a thoughtful means of assessing the Piagetian hypothesis that affective development and cognitive development are interdependent. In addition, it may help to point the way to tests of the similar sequence hypothesis in behavioral domains other than cognitive development as it has traditionally been construed.

Research on the preoperational–concrete operational transition—the Temple longitudinal study. The third longitudinal study reviewed here is by far the broadest in scope. In this ongoing investigation, Stephens and her colleagues (Stephens, 1974; Stephens, Mahaney, & McLaughlin, 1972; Stephens et al., 1974) have conducted biennial assessments of the performance of retarded and nonretarded persons on a variety of Piagetian tasks. The sample included 75 retarded subjects (IQs of 50–75) from special education classes and 75 nonretarded subjects (IQs of 90–110) from the same Philadelphia schools. In the first wave of testing, the age range in both subject groups was 6–18 years. Results from the first two waves of testing have now been reported and are discussed here within two content categories:

Moral judgment. The Temple battery included 11 measures designed to assess three aspects of moral judgment: (a) the relative weight assigned to intent versus consequences in judging the seriousness of a misdeed, (b) awareness of the injustice of punishing an entire group for the acts of only one or a few members, and (c) the ability to judge the relative fairness of various types of punishment including retributive and reciprocal justice. To determine whether judgment along these three dimensions follows the same developmental course in the retarded as in the nonretarded, Mahaney and Stephens (1974) examined changes in scores on the 11 component measures over the 2-year period from the first to the second wave of testing. They found that on 1 of the intent-versus-consequences measures the retarded group showed a nonsignificant decline in score (i.e., they made slightly less mature moral judgments according to the scoring criteria adopted by the authors) and that on 1 of the group punishment items nonretarded subjects showed a nonsignificant decline. On the 9 remaining items the direction of change was the same for both the retarded subjects and the nonretarded subjects; this similarity extended to 2 items on which both groups showed significant de-

clines in score, raising questions about the scoring of these particular items.

Inhelder (1943/1968), in a study described earlier, referred to certain "oscillations" in the reasoning of the retarded. It is of some interest to note that Mahaney and Stephens (who was the translator of the Inhelder book) reported oscillations, that is, instances when "the improvement which occurred in one area of moral judgment was not maintained when opinions were solicited on another, but similar, situation" (Mahaney & Stephens, p. 137), in both retarded and nonretarded subjects. There is some indication that such oscillations may have been somewhat more frequent in the retarded group. One line of evidence that suggests this possibility comes from Mahaney and Stephens's analysis of change scores for three separate age levels within both the retarded and the nonretarded samples. Of the 29 change scores reported for the nonretarded groups, 20 were increases (11 significant), 7 were decreases (3 significant), and 2 showed no change. Among the retarded subjects, 17 change scores were increases (7 significant), 11 were decreases (4 significant), and 1 involved no change. However, when retarded comparison groups were staggered in order to broaden the age difference involved in age group comparisons, for example, by comparing Phase 1 6–10-year-olds with Phase 2 12–16-year-olds, the only items showing a decrease with age were the two that showed a decrease in nonretarded subjects as well. Overall, the report by Mahaney and Stephens (1974) suggests that although growth in moral judgment concepts among the retarded may be "torporific and sporadic" (p. 141), the direction of development is the same for both retarded and nonretarded persons.[4]

Conservation, classification, symbolic imagery, and formal operations in the Temple study. The Temple investigation (Stephens, 1974; Stephens et al., 1972; Stephens et al., 1974) also included 29 measures of cognitive development across four broad conceptual domains: (a) conservation (of substance, length, weight, continuous quantity, and volume, as well as term-to-term correspondence), (b) logic classification (class inclusion and class intersection, and relative thinking measured by the brothers–sisters and right–left tests), (c) operativity and symbolic imagery (tests involving imagined rotations of objects through space, transferring from two to three dimensions, and changing one's perspective on a stimulus), and (d) combinatory logic (Piaget & Inhelder's 1956, combination of liquids task). Explanations given by subjects on each of the 29 items were scored on a 9-point scale that took into account, among other things, the degree to which the subject wavered between a correct and an incorrect answer and the degree to which reversibility was shown. Stephens and McLaughlin (1974) reported on changes in scores on the 29 measures over the 2-year period separating the two waves of testing. They found that the nonretarded group showed improvement on all 29 measures, with 25 statistically significant; the retarded group also improved on all 29 measures, with 26 statistically significant. This finding indicates that the direction of development on these Piagetian reasoning tasks was similar in the retarded and nonretarded groups. In another report following the second wave of the Temple study (Stephens et al., 1972), the Piagetian reasoning tasks were rank ordered with respect to the MAs at which 50% of the subjects (in the retarded and nonretarded groups separately) made correct responses. As Stephens et al. indicated, the order of difficulty for both subject groups was generally consistent with previous findings that conservation of substance precedes conservation of weight

[4] Whether this apparent similarity in the direction of development is actually a function of an invariant, stagelike progression is thus far an open question because of the questionable nature of the measures themselves. In a critique of this portion of the Temple longitudinal study, Kohlberg (1974) maintained that Piagetian moral judgment measures used in the Temple study do not even warrant detailed longitudinal analysis, because

> Piaget himself does not consider that his moral judgment measures yield genuine stages, nor do they pair up with his logical stages in ways compatible with his current thinking about cognitive stages . . . . Empirical research confirms the fact that Piaget's moral stage measures do not meet the criteria of structural stages which his logical stages do meet. (p. 142)

This being the case, it is appropriate to be cautious about what one concludes with respect to the moral judgment portion of the Temple investigation.

and that conservation of weight precedes conservation of volume. In addition, although the ranks were rather crude because MA levels were listed in whole years and because not even the most ardent Piagetian would expect all 29 items to form an orderly developmental scale, it is interesting to note that our own calculations yielded a Spearman rho of .634 between the rank order given for the retarded group and that given for the nonretarded group.

The preceding data are consistent with the similar sequence hypothesis, as far as they have been taken, but they could be taken considerably further. With the one exception mentioned in the preceding paragraph, there has been no apparent effort thus far by the Temple investigators to check their findings against specific developmental stage sequences such as the horizontal decalages reported for nonretarded subjects in previous Piagetian research (Kohlberg & DeVries, 1971; Nassafat, 1963; Siegelman & Block, 1969; Smedslund, 1964; Uzgiris, 1968). Moreover, there has been a persistent inclination to report data in terms of group means, rather than in terms of the number of individuals (retarded and nonretarded) who show specific developmental patterns. This latter type of analysis is the unique province of longitudinal research and can only be approximated indirectly by scaling procedures in research of the nonlongitudinal variety. There is some indication (see Stephens, 1974) that efforts to profile individual performance changes over time and to cross-validate specific vertical and horizontal decalages will be forthcoming from the Temple investigators. Such efforts are needed if the investigators are to fully capitalize on the power of their longitudinal design.

Status of Evidence on the Similar Sequence Hypothesis

Only 1 of the 3 longitudinal studies reviewed —the Wohlhueter and Sindberg (1975) investigation of object concept substages—produced findings inconsistent with the similar sequence hypothesis. In that investigation a distinct subgroup of 10 (out of 49) children showed apparent atypical developmental sequences, and most of these children showed anomalous EEG patterns. This finding may indicate that brain wave anomalies can be associated with atypical developmental patterns. Alternatively, the EEG abnormalities may simply have been associated with attentional and other deficits that interfered with accurate assessment of substage levels in children whose actual development was consistent with the similar sequence hypothesis. The latter interpretation has special credence in the area of object concept assessment, in which procedures demand that the subject sustain attention to an object long enough to seek after it once it has been removed from the preceptual field. Of the 28 nonlongitudinal studies reviewed, only 4 contained a finding inconsistent with the similar sequence hypothesis, and in each of these studies the inconsistent finding was relatively minor and was alone among a number of findings supporting the hypothesis. Furthermore, the questions raised generally concerned rather fine-grained steps or substages within horizontal decalages on which studies of nonretarded subjects alone have not always agreed.

These facts, plus the measurement problems inherent in these experimental procedures, make the degree of consistency in the findings of these 31 studies rather striking. Positive findings have now been reported in conceptual areas that include sensorimotor spatial concepts, object permanence, causality, imitation, affective responding, identity and equivalence conservation (of many properties), seriation, transitivity, moral reasoning, comparison processes (or gross, intensive, and extensive quantities), time, space, relative thinking, role taking, mental imagery, geometric concepts, and classification and class inclusion. For the 31 studies spanning this list of conceptual areas, the great preponderance of the evidence is consistent with the hypothesis that retarded and nonretarded persons traverse the same stages of development in the same order, differing only in the rate at which they progress and in the ultimate ceiling they attain. The hypothesis seems to be generally supported in studies of retarded individuals, regardless of etiology, with the possible exception of individuals suffering from pronounced EEG abnormalities.

Quality of the Evidence

Having said this, we believe it is important to comment on the quality of the available evidence and to offer suggestions for improving it. Cross-sectional data relevant to the similar sequence hypothesis have most often been presented in ways that provide only the weakest inferential power. A table displaying the percentage of subjects at each age level who pass each Piagetian item can yield only a rather faint glimmer of developmental sequence compared with the information generated when each child is classified with respect to specific pass–fail patterns, that is, with respect to response scale types. When such a scaling analysis is combined with calculation of scalogram summary statistics (e.g., Green, 1956; Guttman, 1950), the potential power of the nonlongitudinal design is more fully utilized.

Similarly, the bulk of the longitudinal data we found was presented only in terms of mean difference between experimental groups or changes in group means or percentages over time. As Hunt (1974) has noted, reporting only group summary statistics at Time 1 and Time 2 can mask the fact that some individuals progressed while others regressed over time. Thus, although it is useful to know that the Time 1 and Time 2 means differed in the same direction for retarded and nonretarded groups, such information is no substitute for an analysis of the number of individuals in each group showing specific developmental patterns over time. In both longitudinal and nonlongitudinal research aimed at testing the similar sequence hypothesis, it makes little sense to invest the time and energy necessary to gather potentially relevant data and then analyze the data in ways that fail to capitalize on their full potential.

Suggestions Toward Improved Research

These problems, and others to which we referred earlier in the text, suggest three principles that if widely adopted would substantially improve the quality of evidence on the similar sequence hypothesis.

Structuring Direct Comparisons

A problem with many of the studies reviewed in earlier sections is that their samples included only mentally retarded subjects. In those few instances in which findings of these studies disagree with findings of other studies sampling only nonretarded subjects, the discrepancies are difficult to interpret. This is because of uncertainty over whether the discrepancies reflect actual process differences between the retarded and the nonretarded or whether the differences in experimental methodology across studies are responsible. An obvious way to prevent such difficulties is to expose retarded and nonretarded children within a similar cognitive developmental range to precisely the same procedure by including both groups in the same study. To fail to do so is to risk uninterpretable findings.

Attending to Etiology

The marked heterogeneity of many of the mentally retarded samples described earlier suggests a somewhat opportunistic approach to subject selection or perhaps an approach in which the etiology of retardation is simply not regarded as an important factor. Yet, theoretical considerations discussed early in this article (see also, Weisz, 1976; Zigler, 1969, 1971) point to the need to give special attention to familial retarded children as opposed to those suffering from organic impairment or genetic disorder. Furthermore, Wohlhueter and Sindberg's (1975) report of atypical development in a group of children with a high incidence of EEG anomalies suggests the potential importance of efforts to identify developmentally distinct subgroups within the nonfamilial population. Their analysis illustrates that subgroup analyses can be useful even when they are post hoc.

Promoting Uniformity

Finally, there is a clear need for increased uniformity across studies in the kinds of statistical analyses carried out and in the way statistics are reported. Toward this end, we suggest that every cross-sectional study addressing the similar sequence hypothesis should yield data bearing on the following threefold question:

1. Within the retarded and nonretarded groups do the task items form the same scale, and does this scale show high reproducibility

(à la Guttman, 1950) and a high index of consistency (à la Green, 1956)?

2. Do mean scale scores increase with level of cognitive maturity in each separate subject group (see Kohlberg, 1969)?

3. Do mean levels of success on each individual item increase with levels of cognitive maturity in each separate subject group (see Kohlberg, 1969)?

In longitudinal research, Questions 2 and 3 should also be asked in a way that only longitudinal investigation permits: Over the period spanned by the longitudinal study, in what percentage of individual subjects (from retarded and nonretarded groups) do scale scores and individual item scores (a) increase either smoothly or monotonically, (b) remain stable throughout, and (c) show at least some declines.

These recommended questions are designed to promote greater uniformity, and thus greater comparability, among studies addressing the similar sequence hypothesis. In opposition to such uniformity, one might argue that the degree of consistency in the findings of the numerous studies reviewed here is all the more impressive precisely because of the methodological diversity of the studies. There is some truth to this argument, but only in those cases in which findings support the similar sequence hypothesis. However, we have argued that even in those cases apparent group similarities in developmental sequence may result from a failure to ask the most probing questions of one's data. It seems clear from our review that evidence from the 31 studies currently available offers rather consistent support for the similar sequence hypothesis; it also seems likely that the best evidence has yet to be gathered.

Stability of Aggressive Reaction Patterns in Males: A Review

Dan Olweus
University of Bergen, Bergen, Norway

Considered in the review are 16 studies on the stability of aggressive behavior and reaction patterns. There is great variation among the studies in sample composition, in definition of variables, in method of data collection, and in the ages and intervals studied. Generally, the size of a (disattenuated) stability coefficient tends to decrease linearly as the interval between the two times of measurement ($T_2 - T_1$) increases. Furthermore, the degree of stability can be broadly described as a positive linear function of the interval covered and the subject's age at the time of first measurement, expressed in the age ratio T_1/T_2. The degree of stability that exists in the area of aggression was found to be quite substantial; it was, in fact, not much lower than the stability typically found in the domain of intelligence testing. Marked individual differences in habitual aggression level manifest themselves early in life, certainly by the age of 3. It was generally concluded that (a) the degree of longitudinal consistency in aggressive behavior patterns is much greater than has been maintained by proponents of a behavioral specificity position, and (b) important determinants of the observed longitudinal consistency are to be found in relatively stable, individual-differentiating reaction tendencies or motive systems (personality variables) within individuals.

What has become known as the consistency issue has been the subject of recent lively discussions in the professional literature of psychology. This issue, which has often been presented in an overly simplified way, concerns a whole complex of problems, and it is obvious that different forms of consistency can be conceived of (cf. Olweus, 1974). In the recent discussions, the main emphasis has been on the question of cross-situational consistency (see Endler & Magnusson, 1976), which primarily concerns the extent to which individuals in a group retain their relative positions on a certain dimension or characteristic across various situations, conditions, or sources of data at approximately the same point in time. This issue seems to be far from settled, and in many ways the debate has been confusing, characterized by strong emotional reactions, stereotyped presentations of different theoretical positions, and methodological mistakes (for critical analyses, see, e.g., Block, 1977; Epstein, 1977; Golding, 1975; Olweus, 1977b). In the general debate, the issue of longitudinal consistency or stability—which concerns the extent to which individuals in a group retain their relative positions on a certain dimension or characteristic (or similar dimensions or characteristics) for measurements at different periods of time—has attracted much less attention. Mischel (1968, 1969) however, dealt with the issue at some length and concluded that there is generally little longitudinal (as well as cross-situational) consistency in noncognitive personality dimensions (with the exception of self-descrip-

---

This article is based on invited addresses given at the International Conference on Psychological Issues in Changing Aggression, Warsaw, Poland, July 9–14, 1976, and at the International Congress of Psychology, Paris, France, July 18–25, 1976. The author's research reported in this article was supported by grants from the Norwegian Research Council for Science and the Humanities and the Swedish Council for Social Research.

I want to thank Jack Block for valuable comments on an earlier draft of this article.

Requests for reprints should be sent to Dan Olweus, Department of Psychology, Box 25, N-5014 University of Bergen, Bergen, Norway.

tions on trait dimensions). But the empirical material presented by Mischel in support of his position appears both meagre and selective (see also, Block, 1977). Considering the general importance of the question of longitudinal consistency for personality psychology, it seems valuable to take a closer look at the empirical evidence available. Here this is done for one particular area of research, aggression, which no doubt represents an important behavior system in psychology. Aggression was included among the areas reviewed by Mischel.

Furthermore, the general usefulness of personality concepts involving relatively enduring internal factors or properties of individuals has recently been questioned. For instance, Krasner and Ullmann (1973) tried to demonstrate that the concept of personality is superfluous as a descriptive or explanatory term. They wrote, "The more we know about antecedent, current, and consequent conditions, the less likely we are to use the concept of personality" (p. 489). Similarly, but from a partly different point of view, Shweder (1975) attempted to show that a personality concept in its individual difference sense is of little value and relevance. Also in consideration of these and similar views, it is important to examine the evidence on the stability or continuity of aggressive behavior over time. Such data no doubt will help to shed light on the question of the general utility of assuming a relatively enduring personality system or at least certain more stable subsystems within the individual.

The general purpose of this article is twofold. One goal is to get a picture of the degree of stability obtaining in the area of aggression, as manifested in longitudinal studies of aggressive reaction patterns in males (with the exclusion of self-reports; see below). The main conclusions on this point are presented under the headings of General Description of Results and More Specific, Descriptive Conclusions. A second purpose is to interpret these stability data with a particular view to the possibility of considering them as partly reflecting relatively stable, individual-differentiating reaction tendencies within individuals. Furthermore, the empirical stability data and the suggested interpretations are briefly related to the views expressed by proponents of a behavioral specificity position such as Mischel (1968, 1969) and by critics of personality concepts such as Krasner and Ullmann (1973). This goal is pursued in the sections entitled Interpretation of the Stability Data and Conclusions.

With regard to the second purpose, it should be pointed out that I am generally sympathetic to the view that personality variables in terms of relatively stable, individual-differentiating reaction tendencies may be important (but by no means the sole) determinants of an individual's aggressive behavior (see, e.g., Olweus, 1969, 1973b, 1978). This point of departure is not likely to have influenced the present data gathering and data analysis procedure. However, it seems fair to state at the outset that the analysis in the interpretative section, which leaves somewhat greater room for judgment, has been approached from this perspective.

Coverage of Review

This article is a shortened version of a review presented elsewhere (Olweus, Note 1). In the more complete report relatively detailed descriptions of all studies considered are given. Because of space limitations, such descriptions are provided here for only three reports—one with preschool subjects, the second with subjects of school age (two studies in one article), and the third with adults. However, summary data on method of observation, age and number of subjects, interval beteen measurements, and so on are presented in Table 1 for all studies reviewed.[1]

The focus of the present review is on longitudinal studies of aggressive behavior and reaction patterns, as observed or inferred by individuals other than the subjects themselves. It is important to note that the present review thus does not include studies centering on the stability of self-descriptions

[1] Readers who are interested in detailed information on the studies not described in the present article can obtain a copy of the more complete report by writing to the author.

Note. T_1 = time of first measurement; T_2 = time of second measurement.
[a] Samples on which stability correlations were based generally included males only, except where indicated by a superscript.
[b] Subjects were 18 males and 18 females.
[c] Subjects were male and female.
[d] Subjects were 29 males and 24 females.
[e] See Olweus (Note 1) for details.

on personality questionnaires, self-ratings on trait scales, and similar self-report devices. The stability of this kind of data has often been considered quite substantial (although the self-descriptions are often considered tenuously related to the actual behavior to which they refer; see, e.g., Mischel, 1968, 1969). Some additional comments on the stated guidelines for inclusion in the review are in order.

In most cases the term *aggressive* was used by the original investigator in his or her specification of the variable under study. By and large, these specifications seem to be in accordance with the definition of an aggressive response, given elsewhere (Olweus, 1973b) as

> any act or behavior that involves, might involve, and/or to some extent can be considered as aiming at, the infliction of injury or discomfort; also manifestations of inner reactions such as feelings or thoughts that can be considered to have such an aim are regarded as aggressive responses. (p. 270)

Although most studies reviewed concern data on aggressive interpersonal behavior, some variables deal primarily with aggressive reactivity (e.g., "over-reactive to minor frustrations; irritable"; Block, 1971). Occasionally an author has assigned a variable to the aggressive behavior system that is not included here. This is the case with variables such as competitiveness, dominance, and repression of aggressive thoughts, which are more indirect manifestations of aggressive (and other) tendencies or may be assumed to reflect conflict over, or inhibitions against, aggressive tendencies rather than the aggressive tendencies themselves.

As mentioned, the stated guidelines also imply that studies concerned with the longitudinal stability of inventory responses, self-ratings, and so on are not considered in the review. In one of the included studies (Block, 1971), however, such self-report data were used in combination with other sets of data as a basis for clinical ratings. Longitudinal studies in which projective instruments constituted the only source of data (if such studies exist in the aggressive-motive area) are also excluded from consideration. The exclusion of stability data derived from the latter two data sources makes the material for review somewhat more homogeneous. This, however, does not preclude a substantial variation in a number of respects among the studies considered, as becomes evident.

A further criterion for inclusion in the review is that the degree of stability of the data has been expressed in the form of a correlation coefficient or that such a coefficient can be derived from the reported data in a meaningful way. Accordingly, studies in which only significance tests between discrete groups have been presented are excluded. Furthermore, since the main focus is on the degree of stability/change in behavior rather than on the direction of possible changes, no attention is paid to differences in mean levels between different periods of time; besides, such data are often not available in the reports.

It has been possible to locate 16 studies comprising 16 independent male or mixed samples of subjects for which stability data have been collected. (The 4 studies on mixed nursery school groups are considered here to consist of 1 sample each.) These 16 studies have been described in 14 publications. One of the studies is English (Farrington, 1978), two are based on Swedish samples (Olweus, 1977a), and the rest used American subjects.[2] In some studies, however, the same sample was employed for the determination of several stability correlations covering different periods of time. A total of 24 stability coefficients are available.

In a limited number of studies (six) there was also an independent female sample from which stability data were collected. The female samples are not considered in the present context (except for a brief mention in Footnote 6).

The discussion of the criteria for exclusion of studies from this review may give the impression that there exist a large number of studies on the stability of aggressive behavior and reactions that have not been

[2] It should be mentioned that the search of literature was mainly restricted to books and professional journals written in English.

considered. It is important to emphasize that this is definitely not the case.

Correction for Attenuation

As is well-known, a stability correlation between two sets of measurements on a particular variable is systematically lowered (attenuated) as the result of errors of measurement. Accordingly, the correlation between true or error-free scores on the same variable is higher than that between fallible scores. If the reliabilities of the two sets of measurements are known, the formula for the correction for attenuation can be used to compute the disattenuated correlation, that is, an estimate of the correlation between corresponding true or perfectly reliable scores. The attenuation formula is as follows: $r_{tt} = r_{xy}/(r_{xx} \cdot r_{yy})^{\frac{1}{2}}$, where r_{tt} is the correlation between true scores of x and y, r_{xy} is the obtained correlation between x and y, and r_{xx} and r_{yy} are the reliability coefficients of x and y (see, e.g., Lord & Novick, 1968). It should be noted that the sampling error of coefficients corrected for attenuation is greater than that of uncorrected coefficients of the same size (Thouless, 1939). Accordingly, it is reasonable to expect disattenuated coefficients to occasionally exceed unity as a function of sampling fluctuations, particularly if the size of the sample is relatively small. Correlation coefficients corrected for attenuation should always be considered only approximate in character.

In spite of the latter circumstances, disattenuated coefficients can be very useful and under certain conditions are the most appropriate measures to employ. If for instance, a number of stability correlations are to be compared and they are based on data of varying reliability, attenuation correction will make the coefficients more directly comparable. Furthermore, if the researcher's primary interest is in the relationship between the true rather than the obtained scores, for example, in the stability of the underlying function(s) in contrast with the actual predictive power of the fallible measurements, a disattenuated coefficient is the correct measure to use (see, e.g., Block, 1963, 1971; Lord & Novick, 1968; Thouless, 1939). For both these reasons, attenuation-corrected coefficients are reported in the following review in addition to the uncorrected raw correlations. Most of the theoretical analyses and conclusions are based on disattenuated coefficients.

Relatively little has been written in the psychometric literature with respect to the type of reliability coefficient to be used in the denominator of the correction formula. However, the general principle to follow seems clear and is stated as follows by Lord and Novick (1968):

> If we are to use the correction for attenuation precisely, we must use it only in conjunction with an experimental design that assures that essentially no more or less error variation is introduced into the estimate of r_{xx} and r_{yy} than is introduced into the estimate of r_{xy} [notation changed in accordance with usage here]. (p. 138)

Since many sources contribute to variations among observations (Lord & Novick, 1968, p. 140), the application of the stated principle to a concrete situation is not always simple and straightforward. In general, the most serious error in the present context would occur if the disattenuated coefficients were overcorrected or inflated as a result of too low, deflated reliability estimates. In some of the studies reported here, several reliability estimates were available for possible use in the attenuation formula. In addition, some studies presented either incomplete reliability information or none at all, and so "best guesses" about the reliability estimates had to be made. In such decisions care was taken to settle on reliability estimates that seemed too high rather than too low, in order to avoid the risk of having inflated, disattenuated coefficients. Exact information about the reliability of the measures was not available in some studies, of course, resulting in a somewhat greater uncertainty as to the correct size of the disattenuated coefficients in these studies. It should be noted, however, that the guesses made were of an informed character, as reliability information from similar studies was used. The number of stability coefficients for which best guesses about reliability estimates were made amounted to 5 out of 24 (Em-

merich, 1966; Farrington, 1978; Jersild & Markey, 1935; Martin, 1964; Patterson, Littman, & Bricker, 1967). In all probability, the potential error introduced by this procedure is not great and in any event, because of the strategy adopted, is not likely to have resulted in inflated coefficients.

Aspects of Studies to Be Considered in the Review

To arrive at relatively specific conclusions, it was considered necessary to present the studies under review in some detail. A description of the samples and of the procedures employed in collecting the data is provided, including an at least approximate indication of the definition of the variables studied or of possible interest. In the few cases when a variable of potential relevance has been excluded from the review, the reasons for the decision are given (in the unabridged report, Olweus, Note 1). The ages of the subjects at the time of the first (T_1) and later (T_2, T_3, etc.) measurements are also reported. In some situations, however, a particular problem arises with respect to the subjects' age. This occurs when the material on which the judges' assessments were based does not refer to a specific point in time but covers a period of several years. To relate the size of the stability coefficients to the interval between the two times of measurements (or more precisely, the times to which the measurements refer), the "exact" age of the subjects must be determined. In establishing a rule for the determination of the exact age in such cases the following line of reasoning was applied. It was assumed that a judge who was to assess, for example, archival material or a retrospective interview embracing several years, would have given relatively more weight to information pertaining to the end of the period covered. Accordingly, it seemed reasonable to fix the exact age as 1 year minus the subject's age at the end of the period in question. For example, when the archival material in a particular study referred to the period between ages 3 and 6, the exact age of the subjects was taken to be 5 years. The stated rule was applied in 4 out of 16 studies, or to 9 of the 24 periods for which stability correlations were reported.

Furthermore, the studies reviewed were scrutinized for information regarding environmental changes during the interval from the first to the later time of measurement. Such data are of relevance when it comes to interpreting the stability results obtained. Although information on this point is seldom detailed or individualized, it may give a rough idea of the degree of environmental change characterizing the periods covered.

The reliabilities of the measures or best estimates of such measures are, of course, presented in addition to obtained and attenuation-corrected stability coefficients.

In two of the studies (Block, 1971; Kagan & Moss, 1962) it was natural and possible to compute stability correlations for composite variables, consisting of two components. This was done by means of Spearman's (1913) formula for the correlation of sums (see Olweus, Note 1).

It should be noted that these composites represent aggression variables of greater scope and generality than their components. No doubt it is of considerable theoretical interest to assess the stability of such more generalized variables. They may be of particular value and relevance if the interval separating the two times of measurement is long and there is some uncertainty about the conceptual equivalence of the different variables being used at the different periods of time.

The review briefly presents data, where available, about relationships between the aggression variables studied and information from other, independent modes of measurement. Although incomplete, this information provides some idea of the concurrent, predictive, and construct validity of the data and concepts under study. By this procedure, the reader obtains a better basis for evaluating the adequacy of the conclusions reached. The procedure also furnishes some evidence on the degree of cross-situational consistency, in the sense of the amount of correspondence between aggression data from different, independent sources or modes of measurement.

Description of Selected Studies

Jersild and Markey (1935)

In this early study the behavior of each of 54 children aged 2–4 years (*M* age = 3 years) was recorded during 10 distributed 15-minute periods of free play. The children, 30 boys and 24 girls, were enrolled in three different nursery school groups. Approximately 9 months later 24 of these children were observed again with the same method and during the same number of sessions. The subjects were still divided in three different groups, a total of some 54 children. Relatively marked changes in the peer group composition took place from the first to the second time of observation, particularly for two of the groups (B and C).

The reliability of the observations, as a measure of the adequacy of the sampling of behavior (generalizability across sessions and, to some extent, observers), was determined in several different ways. For the variable of primary interest in the present context, frequency of being the aggressor, the Spearman-Brown corrected coefficients varied between .31 and .90 at the first period of observation, although the majority of them were above .70. At the second period, the two stepped-up coefficients reported were .81 and .55. As a best estimate of the reliability of the observations, a value of .80 was used for both periods of time and was inserted in the formula for attenuation correction of the stability correlation. It can also be mentioned that the percentage of agreement between independent observers of the same behavior sessions was generally high, amounting to 96% in the case of frequency of being the aggressor. Five different observers collected data in this study, although one of them obtained more than half of all the records.

The rank-order correlation (rho) for stability over the 9-month interval was .70 when calculated for all 24 children. When correlations were determined separately for the different groups (*n* varying from 7 to 15), the coefficients were even higher (.71–.88). After correction for attenuation the stability correlation of .70 amounted to .88.

Teacher ratings on a selection of the behavior categories employed were also secured for 35 of the children, permitting a study of the relationship between the behavioral observation variables and independent rating data. Although the ratings and the behavior observations were separated by an interval of several months, the average correlation (for two groups) was .54 for frequency of being the aggressor. The corresponding correlation for the related variable, frequency of physical acts of combat, was .63. If these two variables were combined into a more general composite aggression variable and a similar composite measure were formed for the behavioral observations, the correlation very likely would amount to .75 or more (all the data necessary for carrying out the calculations were not available in the report).

Olweus (1977a)

Two short-term longitudinal studies concerning a 1-year and a 3-year interval, respectively, were conducted by Olweus (1977a) on two samples of Swedish adolescent boys. In both studies the same two 7-point peer-rating scales were used; they concerned unprovoked physical aggression against peers ("He starts fights with other boys at school," abbreviated *start fights*) and verbal aggression against a mildly criticizing teacher ("When a teacher criticizes him, he tends to answer back and protest," abbreviated *verbal protest*). Each boy who served as a rater assessed all the boys in his class by placing cards with the names of his classmates below the points of the scale that referred to different frequencies of occurrence (from *very seldom* to *very often*). The rating procedure was individually administered.

In Study 1 the number of raters in each class was three on both occasions, at Grades 6 and 7. In the second study the number of raters in different classes varied somewhat, the average number being four at Grade 6 and five at Grade 9. In general, the raters were chosen on the basis of random selection from each class. Approximately a third of the raters on the second occasion had also served as raters in Grade 6. To examine if memory effects affected the ratings of iden-

tical raters, a special analysis was conducted in Study 1. This analysis gave no evidence that partial use of the same raters on both occasions inflated stability correlations. Also, the disattenuated coefficients for completely independent rater groups at Grades 6 and 7 were almost identical with the results for rater groups who had one rater in common (see Olweus, 1977a, Footnote 3). Since no memory effects were detected for a 1-year interval, such effects can safely be disregarded in Study 2, which covered a 3-year interval.

The subjects of the first study consisted of 85 boys from 7 classes who were rated at the end of Grade 6, when their median age was 13 years, and also 1 year later. In this study only small changes in the composition of the peer groups took place between Grade 6 and Grade 7. All classes, however, had new teachers at Grade 7. Study 2 comprised 201 boys from 18 classes who were rated at the end of Grade 6 and also 3 years later at the end of Grade 9, when their median age was 16 years. The subjects constituted roughly 75% of the whole population of school boys in the community at these grades. They represented a good deal of variation with respect to socioeconomic factors (relatively representative of greater Stockholm). At Grade 6, the 18 classes comprised a total of 214 boys. Three years later, 13 of these boys has disappeared from these schools and 27 new boys had entered the classes. The new boys constituted roughly 12% of the boys then in the classes at Grade 9. Two classes mentioned later underwent marked changes in the composition of the peer group. Furthermore, all classes had new teachers at Grade 9, and 11 of the classes had moved to other school buildings. A certain amount of environmental change thus occurred for this sample from Grade 6 to Grade 9.

The Spearman-Brown corrected reliability coefficients were estimated as .80 for start fights and as .82 for verbal protest in Study 1. In the second study the corresponding coefficients were .83 and .86, respectively, for average ratings of four raters (Grade 6) and .86 and .88, respectively, for five raters (Grade 9). In Table 1, average reliability estimates for the two variables were given.

The stability correlations in Study 1 were .81 for start fights and .79 for verbal protest. After correction for attenuation these coefficients amounted to 1.01 (rounded to 1.00) and .96, respectively. In Study 2, covering a 3-year interval, the uncorrected stability correlations were .65 and .70, respectively. The disattenuated coefficients were .77 and .81, respectively. It should be noted that to make the ratings from different classes more comparable, the average ratings were converted within each class to standard scores (Z scores). By this procedure differences in mean level and in variability between classes and grades were eliminated. It can also be mentioned that scatterplots of the stability correlations in both studies showed the relationships to be regular and clearly linear in form.

As mentioned, two classes in the second study are of particular interest from a stability/change point of view. In one of these, the original Grade-6 class, consisting of 10 boys, was split into two at the beginning of Grade 8 (5 boys were transferred to another class for unknown reasons). At the second period of rating, the original class had been augmented by 8 new boys (with no previous connections with one another), which thus represented a very marked change in the composition of the class. This change notwithstanding, the stability correlations for the original 5 boys were very high and were, in fact, even higher than the corresponding correlations for the total sample. Also, the transfer of the 5 boys to a new class consisting of 9 boys did not seem to reduce the stability of behavior of the latter: The across-time correlations for the core of 9 boys in this class were for both variables higher than the coefficients for the whole sample (for details, see Olweus, 1977a).

It should also be mentioned that change of school did not seem to appreciably affect the degree of stability over time. There were small and inconsistent differences between the across-time correlations for the 11 classes who moved to other school buildings and the 7 classes who did not move.

As regards relationship to other data, it can be reported that peer ratings on start fights and verbal protest were used as cri-

terion variables for two factorially derived inventory scales of a newly developed multifaceted aggression inventory for boys (Olweus, 1973b; Olweus, Note 2). In several independent samples, substantial correlations have been obtained between these two scales, the Physical Aggression scale and the Verbal Aggression scale, and peer ratings of the overt aggressive behavior. For instance, the average correlation in two samples of boys ($n = 98$ and 86, respectively) between the Verbal Aggression scale and verbal protest was .49 (.63 after correction for attenuation; see Olweus, Note 2, p. 39). Correlations of approximately the same magnitude (.45) were obtained between the Physical Aggression scale and its natural counterpart, start fights (the correlation was .58 after correction for attenuation). Both of the inventory scales obtained clearly higher correlations with their matching than with their nonmatching rating dimensions, thereby giving evidence of discriminant validity. Still higher correlations were found when these two scales were linearly combined to predict the general aggressive behavior dimension: start fights(Z) + verbal protest(Z). The mean of the coefficients for the two samples mentioned amounted to .53,[3] the highest value being .58 (.67 after correction for attenuation).

The peer-rating data in Study 2 were collected within the framework of a large-scale project concerning bully and whipping boy problems in the school that has been described in detail elsewhere (Olweus, 1973a, 1974, 1978). In this context, the form master or form mistress of each class was requested to nominate possible bullies and whipping boys according to specific criteria. When these teacher nominations were related to independent peer ratings, a very convincing picture emerged. The bullies (21 boys from the entire Grade-6 population) were rated as much more aggressive, both physically and verbally, than randomly selected control boys (60 boys) and the whipping boys (21 boys). For start fights and verbal protest, $F(2, 99) = 24.30$, $p < .0001$, $\epsilon = .56$, and $F = 32.39$, $p < .0001$, $\epsilon = .62$, respectively. Essentially the same findings were obtained in two additional, somewhat smaller samples of boys. These results are clearly consistent with theoretical expectations. It can thus be concluded that a substantial degree of correspondence has been demonstrated between peer ratings on one hand and teacher nominations and self-report (inventory) data on the other.

In the article by Olweus (1977a), the rating data (four different variables) were also scrutinized for the possible presence of rater biases, irrelevant method variance, and so on. An adaptation of multimethod–multivariable analysis showed strong evidence for discriminant validity according to all three criteria proposed by Campbell and Fiske (1959). All in all, it was concluded that the results obtained consistently attested to the validity and general adequacy of the ratings employed in these studies.

Block (1971)

The subjects of this study, discussed in *Lives Through Time* (Block, 1971) were 84 adolescent boys and men and 87 girls and women, participants in the well-known Oakland growth (Jones, 1938) and Berkeley guidance (Macfarlane, 1938) longitudinal studies. By means of the Q-sort method the subjects were assessed for three different periods of time: the junior high school years, the senior high school years, and when they were in their middle 30s (the average age was approximately 34 years). For the two adolescent periods extensive archival data such as school grades, comments and ratings by teachers, ratings of social or interview behavior by staff members, performance on intelligence and projective tests, self-reports of areas of agreement or disagreement with parents, and so on were available. From this material, for each subject "case assemblies" were developed separately for the junior high school and senior high school periods. The information collected during

[3] In Olweus (1973b, Table 3, p. 312), the correlation between verbal aggression(Z) + physical aggression(Z) and start fights(Z) + verbal protest(Z) in Sample B was erroneously printed as .42. The correct value is .47.

intensive interviews (an average length of 12 hours) when the subjects were in their mid-30s constituted the third data set. It should be emphasized that these three data sets were completely independent.

The material for a particular subject at a particular period was assessed (as a rule) by three clinical psychologists, each functioning independently. No psychologist evaluated a subject at more than one age, and to minimize the influence of judge biases, the psychologists were assigned to cases in systematically permuted combinations. The judges expressed their characterizations of each subject by means of the California *Q*-set procedure (Block, 1961, 1971). The California *Q* set consists of some 100 items or variables for psychodynamic descriptions of personality that are sorted by the judge into a forced-choice (approximately normal) distribution. In the Block (1971) study the three independent *CQ* sorts for each subject were averaged. Only the two variables most directly concerned with aggressive reactions and behavior are considered in the present context. These variables are Variable 34 ("over-reactive to minor frustrations; irritable") and Variable 62 ("tends to be rebellious and nonconforming"; see Appendix A in Block, 1971; certain other variables, e.g., Variables 38 and 94, are of some, though less direct relevance). In accordance with the previously stated rule, the "exact" age of the subjects is taken to be 12 years for the junior high school (JHS) period, 15 years for the senior high school (SHS) period, and 33 years at the time of adult follow-up.

Some social data and life events of potential significance from a stability/change point of view can be briefly mentioned. These data, however, are not individual and specific but broadly characterize the subjects as a group. The families of the subjects came from predominantly middle and upper classes (mainly from Classes 1–4 on a 6-step scale). The majority of the subjects (81%) experienced intact families, with both the mother and the father present through adolescence. On the whole, the sample appears representative of the stable, relatively prosperous Berkeley community at the time of the study. The social status of the subjects as adults was similar to that of their parents, but the overrepresentation of the two highest social classes was more pronounced in the subject group. By the time of the adult interview, 95% of the subjects had been married and 19% had been divorced. The majority had also become parents, with an average production of 2.5 children. Roughly half the subjects had served in the armed forces during World War II; the other half were adolescents during this period. Although the Depression hit the families of the subjects when the subjects were relatively young (at the time of or before the junior high school period), this crisis is likely to have been of significance for the personality development of certain subjects. Particularly for the older subjects (from the Oakland growth study), the occurrence of the Depression may have reduced the degree of stability of some personality characteristics from the high school years to the time of adult assessment. All in all, these data suggest that "although typicality cannot be claimed for the subjects, they nevertheless have lived recognizable American lives" (Block, 1971, p. 24) and have experienced the adaptational tasks that face most adult persons in connection with marriage, parenthood, and occupational career. In sum, it seems reasonable to assume that in the lives of the subjects under study, there was a good deal of environmental pressure for change during the 20 or so years from high school to the time of the adult follow-up.

For the male sample, the stepped-up interrater reliabilities (Block, 1971, Appendix G) were .49 (JHS), .68 (SHS), and .77 (adult) for Variable 34 and .82 (JHS), .80 (SHS), and .78 (adult) for Variable 62. The raw stability correlations for Variable 34 ("over-reactive . . .") were .45 for the JHS–SHS period (an interval of 3 years) and .29 for the SHS–adult period (an interval of 18 years; the results for the JHS–adult period were not given in Block, 1971). After correction for attenuation, these coefficients became .78 and .40, respectively. For Variable 62 ("tends to be rebellious . . ."), the

stability correlations for the JHS–SHS and SHS–adult periods were .58 and .29, respectively, and after attenuation correction were .72 and .37, respectively.

To calculate the stability correlations for the (unweighted) composite of the standardized variables, $34(Z) + 62(Z)$, some additional information was needed (see Olweus, Note 1). By means of the formula for the correlation of two unweighted composites previously mentioned, the uncorrected stability correlation for the composite variable, $34(Z) + 62(Z)$, was found to be .54 for the JHS–SHS and .44 for the SHS–adult periods. The corresponding disattenuated coefficients were .69 and .53, respectively.

The values for the composite variables are reported in Table 1. The reliabilities in this table for the Block (1971) study are average values for Variable 34 and Variable 62 (e.g., the reliability estimate of .66 for JHS is the average of .49 and .82).

It should be noted that in the present study, great care was taken to secure adequate and valid information by using independent data sets and sophisticated judges working independently in permuted combinations and by a number of additional checks on potential artifacts such as rater biases and stereotypes. The longitudinal data were also analyzed separately for a number of homogeneous personality types derived via inverse factor analysis. For information on these results, the reader should consult Block (1971).

Summary Data on Studies Reviewed

An overview of the studies can be gained from examining Table 1 and Figure 1. In Table 1 the studies are divided into two groups on the basis of the age of the subjects at the time of first measurement (T_1). Within each group the studies are ordered according to the length of the interval separating the two times of measurement ($T_2 - T_1$). Figure 1 presents in diagrammatic form the disattenuated coefficients as a joint function of the subject's age at the time of first measurement and the interval between the two times of measurement. It should be observed that because of space considerations, the reference axes are broken and the units of measurement are different below and above the breaks.

As mentioned, the number of studies with independent samples of subjects was 16. In 4 studies (Block, 1971; Eron, Huesmann, Lefkowitz, & Walder, 1972; Kagan & Moss, 1962; Kohn & Rosman, 1972) the same or partly the same subjects were used in the determination of more than one stability correlation (but for different intervals); a total of 24 stability coefficients are reported in Table 1 and Figure 1. The average raw and disattenuated correlations were .63 and .79, respectively, for the 12 studies with only 1 coefficient per sample, as compared with average values of .55 and .68, respectively, when all 24 stability determinations were used. Although these two materials are not equivalent with regard to the interval covered and so on, the use of several stability coefficients from a limited number of studies does not seem to have resulted in an overrepresentation of high coefficients. In the following discussion the focus is on the characteristics of and the results for the total material.

The average number of subjects on which the stability coefficients were based amounted to 116. The age of the subjects at the time of first measurement varied from 2 to 18 years, and the subjects were followed for intervals varying from half a year to 21 years. The average interval covered was 5.7 years. The highest (average) age of a subject group at the time of follow-up assessment was 33 years.

As is evident from Figure 1, there has been a concentration on short-term longitudinal studies covering intervals up to $1\frac{1}{2}$ years for subjects below school age. Only two stability coefficients are reported for intervals greater than $1\frac{1}{2}$ years, and these coefficients are based on the same, relatively small sample ($N = 36$). For subjects of higher ages, the intervals covered are more evenly distributed.

The methods of data collection or integration were quite varied (see Table 1). In three studies using nursery school groups, the behavior of the subjects was directly

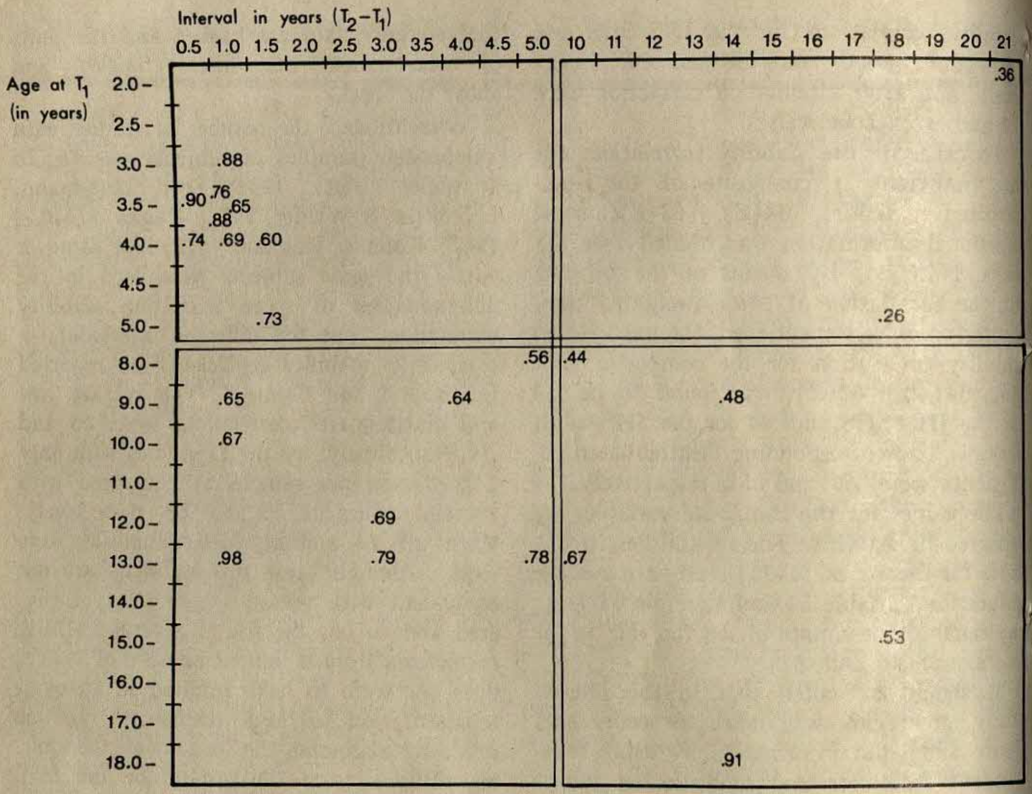

Figure 1. Summary of disattenuated stability correlations for different intervals in years ($T_2 - T_1$) and different ages at time of first measurement (T_1).

observed. Seven stability coefficients were based on teacher ratings, seven on clinical ratings, two on peer ratings, and five on peer nominations.

The variables assessed refer to reactions and behaviors of the subjects in their natural settings, such as nursery school and elementary school. These settings, in which the subjects spent a considerable part of their days at the time of the investigation, can be assumed to represent important sectors of the subjects' lives. The studies by Block (1971), Kagan and Moss (1962), and Tuddenham (1959), which were partly based on archival material collected over several years, provide an unusually broad basis for assessment. In these studies, clinical ratings were used to integrate the rich and diverse material.

Overall, these data suggest a good deal of variation among the studies in a number of important respects. Although a better coverage of certain age periods and intervals would have been desirable, the number of studies is considerable and the average size of the samples quite respectable according to usual standards in psychological research.

Some Methodological Comments

Potential Correlation-Increasing Factors

In four studies using mixed nursery groups (Emmerich, 1966; Jersild & Markey, 1935; Martin, 1964; Patterson et al., 1967), the stability correlations were not computed separately for boys and girls. On statistical grounds this procedure might be expected to lead to somewhat higher coefficients than if the data for the boys had been analyzed separately. On the other hand, in the Block, Block, and Harrington (1974) and Kohn and Rosman (1972) studies, small and negligible differences were found when the sta-

bility correlations were obtained separately for boys and girls and for the sexes combined. The children in these studies were also 3–4-year-olds. The results of the latter two studies thus suggest that combining the sexes in calculating a stability correlation for children of these ages may not have great effect on the size of the correlation coefficient.

Furthermore, there was consanguinity within the sample in one study (Kagan & Moss, 1962), and this fact may have to some extent inflated the raw stability correlations. However, as described in the unabridged report (Olweus, Note 1), certain countermeasures were taken in the present analyses to reduce or eliminate the risks of obtaining too high attenuation-correlated coefficients.

In some studies, partly overlapping, partly different sets of judges/raters were used for the different periods of time (Emmerich, 1966; Eron et al., 1972; Olweus, 1977a; Wiggins & Winder, 1961). However, the evidence presented by Olweus (1977a and p. 860 in the present article) suggests that the inflating effects may be negligible, at least when the time interval between the rating occasions is a year or more.

Potential Correlation-Lowering Factors

Several of the samples studied were probably relatively homogeneous as regards aggressive reactions and behaviors. Furthermore, in longitudinal studies there is usually sample shrinkage over time, and this shrinkage is often systematic. In particular, relatively aggressive individuals are most likely to disappear from the sample studied, as was found in the Eron et al. (1972) study. Such factors tend to reduce the size of the stability coefficients.

In the majority of studies, the conventional product-moment correlation coefficient was employed to express the degree of stability over time. A few studies (Jersild & Markey, 1935; Martin, 1964; Patterson et al., 1967), however, used Spearman's rho, and this index is likely to be slightly lower than the product-moment coefficient (Guilford, 1956). Furthermore, use of a somewhat different technique in forming total scores out of individual items very likely would have given higher stability correlations in at least one study (Wiggins & Winder, 1961).

A central problem in many longitudinal studies is that the conceptual equivalence of the variables or measurement instruments used at different periods of assessment may be considerably less than perfect. The implication is that if more equivalent variables or instruments had been employed, the stability correlations would have been higher. This problem applies to some of the studies considered in this article, for instance, to those in which different variables or instruments had to be used at different periods of time (Kagan & Moss, 1962; Kohn & Rosman, 1973). Generally, this problem seems to be particularly salient when the interval separating the times of assessment is long or the periods assessed represent very different developmental stages.

Finally, and perhaps most importantly, in several studies involving different school and nursery school classes (Block et al., 1974; Emmerich, 1966; Eron et al., 1972; Farrington, 1978; Kohn & Rosman, 1972, 1973; Wiggins & Winder, 1961), the stability correlations were calculated on the basis of the total samples and not as a (weighted) average of the within-class correlations. It can be shown that if the correlations between the means of the classes at the two times of measurement are lower than the (weighted) average of the within-class correlation, the result is a total correlation that is less than the average within-class correlation (cf. Lindquist, 1940, although no proof is given). Often there are good reasons to expect the correlation between the class means to be lower than the average within-class correlation (different raters or sets of raters may develop different, class-relative rating norms and so on), and accordingly, the total correlation will be an underestimate (for theoretical as well as predictive purposes the real interest is in a stability correlation unaffected by differences in class means). There are few reasons for expecting the correlation between the class means to be higher than the average within-class correlation in studies

of the present type. In the second (as well as the first) study by Olweus (1977a), results supporting the above argument were found. The raw correlations for the total sample ($N = 201$) were .55 for start fights and .63 for verbal protest, as compared with .65 and .70, respectively, when weighted average within-class correlations were computed (equivalent to total correlations based on within-class standardized variables). In other studies, the effects of eliminating class differences in mean level (and variability) may be less marked, but nevertheless, such a procedure is most likely to systematically increase the size of the stability coefficients.

All in all, the above considerations suggest that a preponderance of correlation-lowering factors were operative in the studies surveyed, and very likely, many of the stability coefficients reported are underestimates. In addition, when correcting for attenuation, a deliberate strategy was adopted to settle on reliability estimates that were not too low in cases of incomplete reliability information. Accordingly, the stability coefficients on which the following analyses are based are likely to be underestimates (rather than overestimates or "correct" values).

General Description of Results

If the disattenuated stability coefficients are plotted as a function of the interval in years between the two times of measurement ($T_2 - T_1$), a relatively regular picture is obtained (Figure 2). The size of the stability coefficient tends to decrease as the interval covered increases. The trend can be described by the following regression equation: $y = .78 - .018x$, where y is the disattenuated correlation and x is the interval ($T_2 - T_1$) in years. The spread around the regression line (the standard error of estimate, $s_{y \cdot x}$) is .13, and the correlation between the two variables amounts to −.66. The decrease of the regression line is relatively slow (although significant). For an interval of 5 years, the estimated disattenuated stability correlation is .69 and for an interval of 10 years is .60.[4]

For comparison, the linear regression line for data on intelligence test measurements (of the Stanford-Binet type) compiled by Thorndike (1933) is shown in Figure 2. (Thorndike's findings were later corroborated by other researchers and are widely accepted; see, e.g., Anastasi, 1958). In this case the regression line is based on 36 stability coefficients covering intervals up to 5 years. These coefficients were derived from 13 different samples, mainly school-age children (the ages were not given). The average sample size was 111. The regression equation describing the trend in Thorndike's data is $y = .92 - .022x$.[5] The standard error of estimate, $s_{y \cdot x}$, is .08, and the correlation between the variables amounts to −.32 (all measures were recomputed from Thorndike's data and corrected for attenuation; the assumed reliability was .95, in accordance with the first two entries in Thorndike's table). As evident from the figure and the regression line, the stability of intelligence measures is generally somewhat higher than the stability of aggression variables, but the decrease of the regression line is slightly steeper for intelligence than for aggression. Extrapolating from the regression line for intelligence, the difference between the estimated coefficients would be only .10 for an interval of 10 years (.70 for intelligence and .60 for aggression. Although it may not be feasible to institute very detailed comparisons between the two sets of data, since the ages of the subjects were not given in Thorndike's article, it can be generally asserted that there is a substantial degree of stability over time for aggression[6] as well as for intelligence and that the difference in stability

[4] In calculating the regression equation each stability coefficient was given equal weight. Weighting of the stability coefficients according to the number of subjects on which they are based makes little difference. The same is true for the use of Z values instead of r values. For the raw correlations (unweighted) the regression equation is $y = .63 - .014x$.

[5] The regression equation for the (unweighted) raw correlations is $y = .87 - .020x$.

[6] It can be noted in this context that the stability of aggressive reaction patterns in females also seems to be substantial (if two studies with relatively small samples are excepted), in contrast with what is generally assumed (manuscript in preparation).

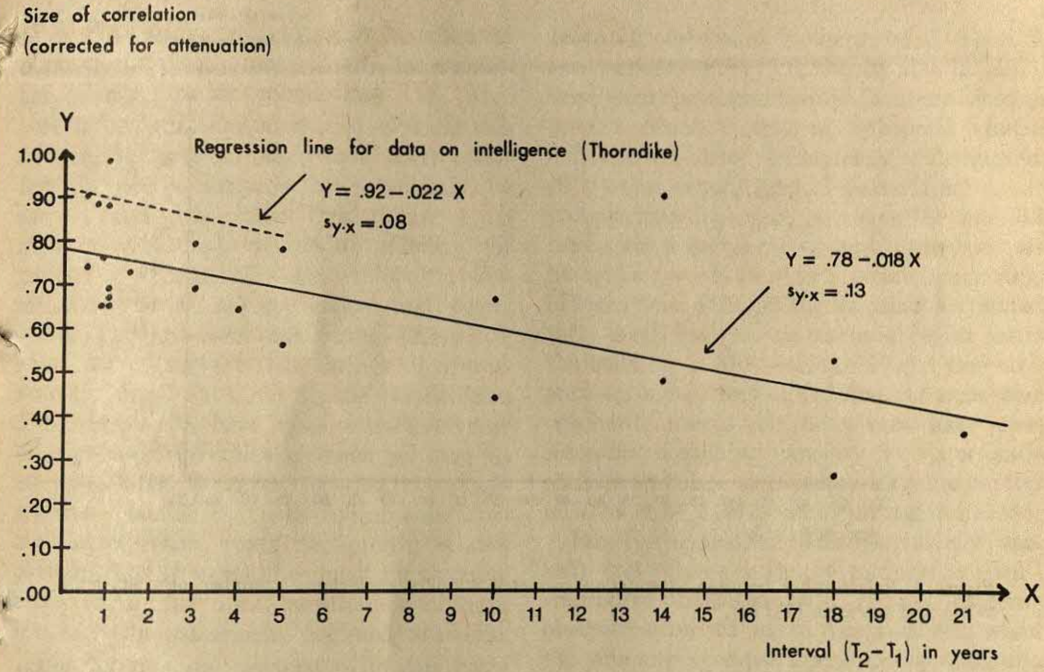

Figure 2. Regression line showing relationship between attenuation-corrected stability coefficients and time interval ($T_2 - T_1$) in years (unbroken line). (The regression line is based on 24 stability coefficients [plotted]. For comparison, the regression line for attenuation-corrected stability coefficients in the area of intelligence is shown [broken line]. This regression line is based on 36 stability coefficients [not plotted]; Thorndike = Thorndike, 1933.)

in the two areas does not appear to be very great.[7]

Although the goodness of fit of the regression line to the data in Figure 2 appears quite acceptable, theoretical considerations and inspection of Figure 1 suggest that the subjects' age at the time of first measurement may be an important parameter in addition to the interval $T_2 - T_1$. One way of expressing the stability correlations as a joint function of the subjects' age and the interval is to form an age ratio T_1/T_2. For a constant age, the age ratio decreases as the interval $T_2 - T_1$ increases. And for a particular interval, the age ratio is lower at a low age than at higher ages. It is theoretically reasonable to expect the stability coefficients to show the same trend as the age ratio, and accordingly, a positive relationship can be anticipated between the age ratio and the disattenuated stability correlations.

The relationship between the two variables shown in Figure 3 is clearly positive, as expected, and the goodness of fit of the regression line ($y = .26 + .617x$) to the data is even better than in Figure 2. This is manifested in a somewhat lower standard error of estimate (.11 compared with .13) or,

[7] In another overview by Thorndike (1940), the subjects in his 1933 article are referred to as school-age children. If in order to make the present data and the intelligence test data as comparable as possible, the regression equation is calculated only for aggression studies on children of school-age and for intervals up to 5 years (the first eight studies in the second section of Table 1), the equation is found to be quite similar to the regression equation for the total set of studies: $y = .80 - .027x$. It can also be noted that if comparisons are made on the preschool level, that is, comparisons concerning the stability of aggressive and intelligence test behavior (Thorndike, 1940, Table 1) over intervals up to a year or so for 3–4-year-old children, the stability of aggressive behavior is found to be as great as or slightly greater than the stability of intelligence test behavior (attenuation-corrected coefficients).

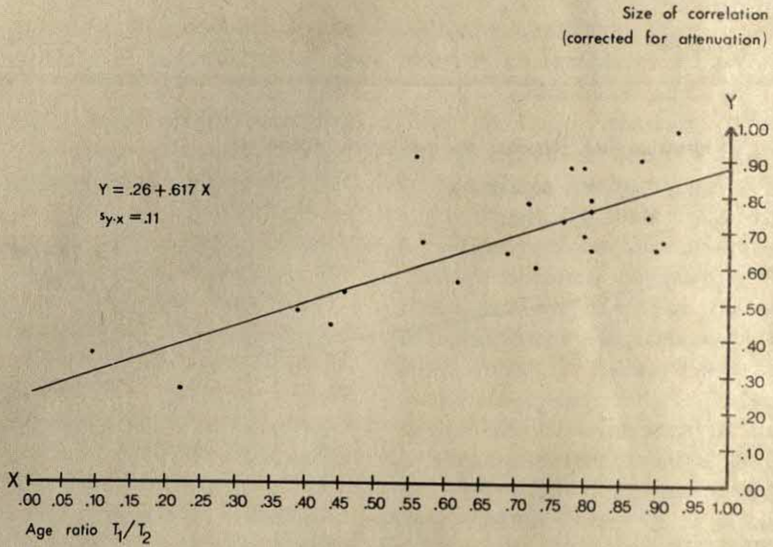

Figure 3. Relationship between attenuation-corrected stability coefficients (number of coefficients = 24) and age ratio (T_1/T_2).

alternatively, in a somewhat higher correlation coefficient (.77 compared with .66).[8] The picture obtained in Figure 3 indicates a good deal of regularity in the relationship between the age ratio T_1/T_2 and the disattenuated stability coefficients (similar results were obtained for the raw correlations). More specifically, the figure shows that the degree of stability in the individuals' relative positions on aggression variables of the type considered here can be broadly described as a linear positive function of the interval between the times of measurement and the subjects' age at the time of the first measurement, expressed in the ratio T_1/T_2.

There is thus less stability or more change in the individuals' relative positions the longer the interval $(T_2 - T_1)$ covered is (particularly if the subjects' age at T_1 is held constant). And for a particular interval $(T_2 - T_1)$, there is less stability or more change the younger the subjects are (although the relation between the stability correlation and the subjects' age is less marked than that between the stability correlation and the interval). The effect, so to speak, of a certain interval is greater for younger than for older subjects. These conclusions appear quite reasonable from a developmental as well as from a common sense point of view.

Since the ages of the subjects were not given in Thorndike's (1933) article, it is not possible to compare the fit of the regression lines for interval versus stability coefficients with the fit of the regression lines for age ratio versus stability coefficients. However, data available from other sources (Anastasi, 1958; Honzik, 1938) suggest that use of the age ratio T_1/T_2 in the intelligence domain, leads to better predictions than the use of the interval $T_2 - T_1$ alone.

More Specific, Descriptive Conclusions

The substantial degree of regularity manifested in Figure 2 and in Figure 3 is particularly impressive considering the great variation among the studies in sample composition, definition of variables, research setting, method of data collection and integration, and the researcher's theoretical orientation. There was also a very great range in the ages and intervals studied. After having emphasized the regularity of the data

[8] The correlation of .77 is in fact slightly higher than the multiple correlation between disattenuated coefficients on one hand and age and interval on the other; besides, use of the age ratio is more meaningful from a theoretical point of view.

as a general finding, it is appropriate to examine the results more closely for a number of more specific conclusions.

It is obvious that marked individual differences in habitual aggression level manifest themselves early in life (certainly by age 3) and may show (see Figure 1) a high or very high degree of stability for periods of at least 1½ years at this developmental level (in nursery school and school settings). Data from one study (Kagan & Moss, 1962) suggest that ratings of aggression variables that refer to the period from 0 to 3 years may have some predictive value of aggression variables assessed as long as 20 years later. However, to what extent aggressive reaction patterns observable during the preschool years can predict related patterns 5 or 10 years later must for the time being remain an open question, since data for such an assessment are not available.

Furthermore, in contrast with the common belief that the method of direct observation gives evidence of much more behavioral specificity and less stability than ratings of different kinds, no such tendencies were found in the present material. The average stability correlation for the three studies using direct observation (Jersild & Markey, 1935; Martin, 1964; Patterson et al., 1967) was .81, which can be compared with the average value of .79 for the three comparable studies by Block et al. (1974), Emmerich (1966), and Kohn and Rosman (1972; first study in Table 1) employing teacher ratings (the average stability correlations for the two sets of studies, using uncorrected coefficients, were .65 and .64, respectively). The comparability of these two sets of studies is manifested in equal average age ratios: both were .83; all studies were based on nursery school or similar groups. Judging from these studies, there seems to be no difference in degree of stability over relatively limited periods of time (up to a year) for aggression data collected by means of direct behavioral observation and teacher ratings.

Passing on to the school years, it is obvious that aggressive reaction patterns observable at ages 8 or 9 can be substantially correlated with similar patterns observed 10 to 14 years later (some 25% of the variance accounted for). It should also be noted that such patterns can with some success predict certain forms of antisocial violent behavior (violent delinquency; Farrington, 1978) that occur 10 to 12 years later.

Aggressive behavior at ages 12 and 13 may show a high or very high degree of stability for periods of 1 to 5 years (from 50% to more than 90% of the variance accounted for). Also, for periods as long as 10 years the stability is high (some 45% of the variance accounted for). Furthermore, aggressive reaction patterns at these ages have considerable predictive capacity for later antisocial aggression, as evidenced by the studies of Eron et al. (1972) and Farrington (1978).

Finally, aggressive behavior (chiefly verbal) and reactivity in the mid-30s are substantially correlated with similar patterns observed some 15 to 18 years earlier, when the subjects were teenagers. Considering the general trend of the stability coefficients and the fact that 52 of the 72 subjects used by Tuddenham (1959) were included in the sample of 171 subjects studied by Block (1971), it is likely that the disattenuated coefficient of .91 reported by Tuddenham is somewhat high because of chance factors. It should be noted, however, that the follow-up data in Tuddenham's study were completely independent of the data on which the adult evaluations in Block's study were based.

When evaluating these results, the general adequacy and validity of the data should also be considered. One should recall that in several investigations a considerable degree of correspondence was found between the aggression variables studied and teacher ratings of the same or related behaviors. This was true for teacher ratings and nominations versus peer ratings (Olweus 1974, 1978; Walder, Abelson, Eron, Banta, & Laulicht, 1961; Wiggins & Winder, 1961) as well as for teacher ratings versus direct behavioral observation (Jersild & Markey, 1935). If these sets of data were corrected for attenuation, the correlation between them very likely would exceed .75, indicating a quite substantial relationship. In some investigations the aggression variables studied also mani-

fested relationships of considerable magnitude with self-report data on similar patterns (Olweus, 1973b, 1978; Olweus, Note 2) and related, but more antisocial forms of behavior (Eron et al., 1972; Farrington, 1978). In addition, clear associations were obtained between two of the peer nomination instruments used in the stability studies and overt aggressive behavior in a contrived, naturalistic setting (Winder & Wiggins, 1964) and in a controlled, experimental situation, respectively (Williams, Meyerson, Eron, & Selmer, 1967). Finally, the possible existence of rater biases and stereotypes was carefully examined in some studies, in particular those by Block (1971) and Olweus (1977a). In the latter study it was concluded on the basis of several different analyses that "the rating data to an overwhelming degree reflect characteristics of the boys under study, rather than the biases and cognitive schemas of the raters irrespective of ratee characteristics" (Olweus, 1977a, p. 1310).

All in all, the above results derived by different methods and under a wide variety of conditions constitute strong evidence for the validity and general adequacy of the aggression data on which the stability correlations were based. They also attest to a substantial degree of cross-situational consistency in the sense that there is a considerable correspondence between aggression data obtained from independent sources or modes of measurement at about the same point in time. (The issue of cross-situational consistency in the area of aggression is not pursued further in the present article.)

It should also be noted that the finding of a considerable degree of stability of aggressive reaction patterns over time seems to be in general agreement with what has been observed in a number of studies of related, but more clearly antisocial forms of behavior (e.g., Conger & Miller, 1966; McCord & McCord, 1959; Robins, 1966; Roff, 1961; Rutter, 1972; Tait & Hodges, 1962).

Interpretation of the Stability Data

The descriptive conclusion that there is a substantial degree of stability in aggressive behavior cannot, however, without further analyses be taken as evidence for the corresponding stability of some reaction tendencies or motive systems within individuals. It might be argued from a situationist point of view (see Bowers, 1973), for instance, that the observed consistency primarily reflects stably different conditions for different individuals in the settings studied. Thus, in the first place, the stated conclusion can be said to apply under typical conditions, that is, under a degree of environmental variation (or stability) and pressure for change (or nonchange) typically found in the settings of the subjects for the periods studied (cf. Olweus, 1977a). Accordingly, it is important to examine the conditions characterizing the settings and periods under study, maybe particularly for the highly aggressive individuals, since their relative lack of change is a prerequisite to high stability coefficients.

In the studies on preschool children little detailed knowledge of changes in the settings is available. However, a good deal of change in the composition of the peer group took place in some studies (e.g., Jersild & Markey, 1935; Kohn & Rosman, 1972, 1973). Furthermore, in the three studies using the method of direct observation (see Table 1), the behavior was observed during periods of free play involving a minimum of situational structure and, in all probability, interaction with a number of different peers. Even if evidence has been presented that a nursery school setting can provide reinforcement of aggressive behavior (Patterson et al., 1967), the same authors have also reported (p. 32) that the highly aggressive children were the most likely to be the target of other children's aggression, that is, to get punished. Furthermore, Jersild and Markey (1935, p. 163) reported that the nursery school teachers interfered with the children's conflicts in about a third of the cases and predominantly in a way that was unfavorable to the aggressor. It should also be recalled that a small number of children accounted for a large percentage of the aggression episodes. It thus seems difficult to explain highly aggressive behavior in these settings as a consequence of situational pull

or primarily as a function of reinforcement. It appears rather that the highly aggressive children in particular were exposed to a certain pressure for change in nonaggressive directions from the teachers.

As regards the subject groups studied in the school setting it can be mentioned that in most cases the classes had new teachers and had moved to other school buildings at the second time of measurement. A relatively large percentage (10% to about 25%) of the original classmates had also been replaced by new peers. In one of the studies (Olweus, 1977a), somewhat more detailed information about changes in the composition of the peer group was available. As previously shown, even very marked changes in two classes did not affect the stability of aggressive behavior of those boys who were in the class at both times of measurement.

Furthermore, it can generally be assumed that there was at least a certain amount of pressure from the teachers and the administrative staff in the direction of modifying the behavior of the habitually aggressive pupils. As evidenced by the substantial stability correlations, such environmental pressure did not seem to be very effective. This finding is in good agreement with the general experience that it is difficult to reduce aggressive and antisocial behavior in preadolescent and adolescent males (see, e.g., Olweus, 1978, chap. 9; Burchard & Harig, 1976). It thus appears that the behavior of highly aggressive boys of these ages is often maintained irrespective of considerable environmental variation and in opposition to forces acting to change this same behavior.

It may be questioned, however, if there are not particular aversive situations or conditions in the school environment of the habitually aggressive boys that might explain their behavior. This question was analyzed in some detail by Olweus (1977a), who drew on the extensive findings regarding a particular group of highly aggressive boys, the bullies previously mentioned (Olweus, 1974, 1978). On the basis of several lines of evidence concerning the possible existence of frustrations, failures, and rejections in the school as well as the presence of other psychological, physical, and socioeconomic conditions of the bullies, it was concluded that "it is very difficult to explain the behavior of the highly aggressive boys as consequence of their being exposed to unusually aversive situations or conditions in the school setting" (Olweus, 1978, p. 136).

With regard to the subjects followed up in their adult years (Block, 1971; Kagan & Moss, 1962; Tuddenham, 1959), the majority went through experiences of potentially great impact on their lives during the interval from earlier to later measurements. Most of the subjects had married, and a certain percentage had divorced; in addition, they had started on and also covered part of their professional careers. A majority of the subjects in Block's study (and probably also in that of Tuddenham) had become parents. Most of them had been in military service, and roughly half of Block's (and the majority of Tuddenham's) subjects had served in the armed forces during World War II. Some of the situations or life events mentioned can be primarily regarded as forced upon the subjects, at least in some respects; others can be mainly considered to be a result of active selection on the part of the subjects. In sum, it is very likely that a good deal of environmental change and also pressure for change of highly aggressive reaction patterns were imposed on the subjects in these studies during the 10 to 20 years separating the earlier and later assessments. In addition, considerable maturational changes can be expected to occur during such a long period for subjects who are only about 10–15-years-old at the time of the early measurement.

When making an overall evaluation of actual and presumed environmental changes and pressures for change during the periods studied, one is, in fact, even more surprised at the degree of stability manifested. As previously concluded, changes in the individuals' relative positions had certainly occurred, both as a function of the interval covered and of the individuals' age at the time of first measurement. And if more detailed knowledge of the conditions and life events facing the individual subjects had been available, maybe more exact predictions about changers and nonchangers could have

been made. In an overall appraisal, however, the primary task confronting the researcher seems to be one of explaining the substantial stability or lack of change in aggressive behavior found to prevail in spite of considerable environmental variation and in opposition to a number of influences acting to change this same behavior.

The relative lack of change is all the more remarkable because highly aggressive behavior often leads to aversive consequences from the environment. Even if psychological and physical advantages can be gained by aggressive behavior in a number of situations, negative effects (such as punishment from the environment) often seem to be equally likely. It can also be argued that many aggressive behaviors, such as bullying or aggressive attacks in a free-play situation, are self-initiated behaviors (cf. Olweus, 1977a). As previously pointed out, it is often difficult to explain the behavior of the highly aggressive individuals as a function of particular aversive conditions or strong situational pull in the immediate, proximal situation in which the aggressive behavior is displayed. In the studies surveyed, there is little evidence supporting a view that stable differences in aggression level are primarily a consequence of consistently different environmental conditions for different individuals in the nursery school, the elementary school and so on. Overall, the above results and analyses strongly suggest that the observed stability over time of aggressive reaction patterns is, to a considerable measure, determined by relatively stable, individual-differentiating reaction tendencies or motive systems within individuals.

Conclusions

In addition to the previous descriptive generalizations, the following conclusions are warranted. They pertain directly to the issues raised in the Introduction.

1. The degree of consistency over time in aggressive behavior is much greater than has been maintained by proponents of a behavioral (situational) specificity position in the personality field (e.g., Mischel, 1968, 1969). It should be noted that the aggressive behavior and reaction patterns studied were observed or inferred by individuals other than the subjects themselves and that several studies (Jersild & Markey, 1935; Martin, 1964; Patterson et al., 1967) used the method of direct behavioral observation. It should also be emphasized that, generally, the substantial degree of stability found can hardly be interpreted as mainly reflecting consistency constructed in the minds of the observers, irrespective of the actual behavior of the subjects.

The across-time stability of aggressive behavior was not much lower than that typically found in the intelligence domain. This finding is worthy of particular emphasis, since the stability of behaviors associated with intelligence and cognitive processes has been generally regarded as impressive and indicative of "genuine continuity" also by proponents of a behavioral specificity position (e.g., Mischel, 1968, pp. 35–36). To avoid misunderstanding, however, I want to make clear that when pointing to similarities between results from the intelligence domain and those from the aggression area, I restrict my comparison to the degree of stability over time. I am in no way implying assumptions about similar developmental and operating mechanisms or, for instance, that the degree of genetic influence is the same in the two areas (see Olweus, 1978, chap. 8).

2. As previously spelled out, the results and analyses strongly suggest that important determinants of the observed consistency in aggressive behavior over time are to be found in relatively stable, individual-differentiating reaction tendencies or motive systems, however conceptualized, within individuals. This conclusion should not be taken to imply that situational factors are considered unimportant for the evocation of aggressive behavior (see, e.g., Olweus, 1969, 1973b). Nor does it imply that aggressive behavior is independent of rewarding and maintaining conditions in the immediate, proximal environment. However, it is contended here that the explanatory and predictive value of such factors has been exaggerated in the last decade; the analyses of the present article clearly suggest that relatively stable, internal reaction tendencies are important determinants

of behavior in the aggressive-motive area and should be given considerably greater weight than has been done recently. (For an overview of how such internal reaction tendencies may develop in the area of aggression, see Olweus, 1978, chap. 8.) In line with this argument, it also seems quite reasonable to assume that the inferred, internal reaction tendencies or motive systems within an individual are essential codeterminants of what the individual will perceive as reinforcing. In fact, the analyses presented suggest that highly aggressive individuals to a considerable degree actively select and create the kind of situations in which they are often observed (cf. Bowers, 1973; Wachtel, 1973).

The stated conclusion can also be interpreted as providing support for some form of trait position,[9] at least in the following sense: The results indicate that the probability of giving an aggressive response in potentially aggression-activating situations, more or less separated in time, or the strength of such responses differs greatly among individuals. In my view, however, the results do not imply that knowledge of an individual's habitual aggression level necessarily leads to good predictions of the behavior of the individual in a particular concrete situation. It has been empirically found, for instance, that the relationship between aggressive responses in different situations (data sources) for certain groups of individuals (with high aggression-inhibitory tendencies) may even be negative (but in a predictable way; see Olweus, 1969, 1973b). To make more accurate predictions for particular situations, it seems necessary to take into account, among other things, the individual's cognitive appraisal of the situation, the aggressive activation value of the situation, the aggression-inhibitory activation value of the situation, the strength of the individual's habitual aggressive tendencies, as well as the strength of the individual's aggression-inhibitory tendencies (Olweus, 1969). Accordingly, I prefer not to interpret the consistency results obtained in terms of a (simple) trait formulation of aggressiveness (see also, Olweus, 1973b).

The preceding analyses and conclusions thus indicate that what are known as personality concepts involving relatively stable, internal reaction tendencies or properties of individuals are useful in predicting and explaining aggressive behavior. Data on longitudinal consistency in other motive systems (e.g., Block, 1971) suggest that this is true also in areas of psychology other than aggression. It appears, then, in contrast with some recent proposals (e.g., Krasner & Ullmann, 1973; Shweder, 1975), that personality concepts and variables referring to relatively stable, individual-differentiating reaction tendencies or properties may be of great value in psychology for many years to come.

[9] It should be noted that it is difficult to speak of trait theory in general, without reference to a particular theorist or a particular motive area. There are obviously many differences and nuances among different theorists.

Evolutionary Scales Lack Utility: A Reply to Yarczower and Hazlett

John P. Capitanio and Daniel W. Leger
University of California, Davis

Yarczower and Hazlett have proposed that evolutionary scaling based on anagenesis (biological improvement) is an acceptable—even desirable—facet of contemporary comparative psychology. We strongly disagree with that thesis. Our criticisms are based on (a) their misconception of anagenesis, (b) inconsistencies in the use of the term *evolutionary grades,* (c) typological thinking, and (d) the lack of utility of evolutionary scales. Reversion to evolutionary scaling by comparative psychologists would disrupt the ongoing synthesis of comparative psychology with other evolutionary sciences.

In a recent *Psychological Bulletin* article, Yarczower and Hazlett (1977) attempted to legitimize the construction of evolutionary scales, suggesting that "evolutionary scales have a place within comparative psychology and do not violate principles of evolution when done properly" (p. 1096). Although evolutionary scaling may have a limited place in analyses of structural features, we believe the concept is inappropriate and potentially misleading in analyses of behavior. Further, it is our contention that the arguments and evidence promulgated by Yarczower and Hazlett are not only internally inconsistent but reflect a serious lack of understanding of the principles of evolutionary biology.

Our criticisms of Yarczower and Hazlett revolve about four main issues: (a) the concept of anagenesis, or biological improvement, (b) the appropriate definition of evolutionary grade, (c) typological thinking, and (d) the utility of evolutionary scales in modern comparative psychology.

Anagenesis

Although most evolutionary biologists agree in principle that anagenesis refers to the evolution of increased complexity in some trait, the term has become diluted since its inception and "has come to be applied to nearly any kind of evolutionary change, whether leading to a marked advance or not" (Dobzhansky, Ayala, Stebbins, & Valentine, 1977, p. 236). Dobzhansky et al. feel that the vast majority of evolutionary events are actually adaptive changes at the same level of complexity.

Yarczower and Hazlett apparently view increased complexity and specialization as corollaries of evolution; they cited Darwin and some older works of Simpson and of Huxley to support this position. Although the former authors have the right to restrict their discussion to anagenesis, it should be recognized that anagenesis is but one of several evolutionary processes. For example, Dobzhansky et al. (1977) have written that the definition of evolution

> must not include the notion that evolution is always progressive, leading inevitably from simpler to more complex forms of life. To be sure, some of the most important evolutionary events have been increases in structural complexity, e.g., . . . the complex sense organs of vertebrates . . . and animal societies . . . . Furthermore, both older and modern theories [of evolution] recognize even degenerations of structure as evolution, provided they are products of adaptive alterations in population-environment interactions. (p. 8)

The evolution of blindness in cave-dwelling fish and the degeneration or structure and behavior in parasites are examples of the adaptiveness of *decreased* complexity. Wilson

Requests for reprints should be sent to John P. Capitanio or Daniel W. Leger, Department of Psychology, University of California, Davis, California 95616.

(1975) has provided a detailed account of the degeneration of the central nervous system and of behavior in parasitic ants compared with their ancestral free-living relatives.

Thus evolutionary change is by no means unidirectional. Because selection pressures often fluctuate, a certain amount of evolutionary backtracking is to be expected. Natural selection can result not only in anagenesis but also in degeneration, in stasigenesis (no change whatsoever), or, more likely, in change without alteration of complexity. It should be remembered that the things of value for organisms are survival and reproduction; evolutionary success is clearly not dependent on complexity per se.

Evolutionary Grades

The term *evolutionary grade*, as used by Yarczower and Hazlett, differs markedly from the definitions given in current major works (e.g., Mayr, 1970; Wilson, 1975). Although all the above authors have agreed that grade refers to the stage of a behavior, anatomical structure, or physiological process, Yarczower and Hazlett (1977) stipulated that to be included in the same grade, animals must be "related by parallel evolution" (p. 1091), that is, must be closely related. But according to Wilson (1975), "Phylogenetically remote lines can reach and pass through the same grades, in which case we speak of the species making up these lines as being convergent with respect to the trait" (pp. 25–26).

The concepts of parallel evolution and convergent evolution, with their implications of closely and distantly related species, respectively, have been a common source of confusion. Kaster and Berger (1977) correctly pointed out that parallelism and convergence can occur in taxa of *any* degree of phylogenetic affinity; that is, the process is of primary importance, and the degree of relatedness is of secondary concern.

But even if one refrains from judging the relative value of the two definitions, Yarczower and Hazlett were at least repeatedly inconsistent in using the term *grade* as they originally defined it. For example, they wrote of birds, mammals, and reptiles as having attained the grade Amniota. By no stretch of the imagination can these classes be viewed as being closely related; there is no doubt however that they have converged on a common strategy. Later, Yarczower and Hazlett diluted their original statements by following up Huxley's (1958) suggestion that the "breadth" of the grade be designated by the lowest common taxon rank of the least related species included in the comparison, for example, grade–order or grade–class (see Kaster & Berger, 1977, for a similar suggestion). Thus, Yarczower and Hazlett defined evolutionary grade differently from Wilson (1975), Mayr (1970), and Dobzhansky et al. (1977); but their use of the term is consistent with the latter authors' definition.

If, for the moment, one ignores Yarczower and Hazlett's (1977) examples and takes their definition of grade as what they actually meant, then they are faced with two major problems. First, their notion of parallelism must be clarified, because the possibility exists that even phylogenetically remote taxa may evolve in parallel. Second, if parallelism is taken to refer only to "closely" related species, they must then consider the distinct probability that they were dealing with homologous traits—a task they explicitly wished to circumvent (p. 1090).

But if one ignores their definition and views their examples as indicative of their position, it is quite clear that Yarczower and Hazlett were dealing with evolutionary convergence, that is, similar phenotypic response to similar selection pressures. Again, however, convergence was explicitly excluded from their thesis.

The failure of Yarczower and Hazlett to unambiguously state their position concerning evolutionary grades can only be taken as an indication that they have failed to establish "a third approach to the study of behavioral evolution" (p. 1088); their approach cannot be distinguished from the other two approaches, namely, the studies of homology and analogy.

Typology

In discussing the level of a particular grade, Yarczower and Hazlett (1977) asked us to keep in mind the representativeness of a particular animal with respect to its higher taxon. Is the cat representative of Carnivora,

the squirrel of Rodentia, and so on? One might well ask, is any species truly representative of a particular higher taxon? The question of representativeness is surely a relative one, and disagreement is certain to exist. Consider an example (from Tinbergen, 1958). If one wished to construct grades based on nesting behavior, one might very well choose the black-headed gull to represent the gull family (Laridae) and then place the gulls in the grade *colonial ground nesters*. Alternatively, one might choose the kittiwake as the representative and therefore place the gulls in the grade *colonial cliff nesters*. To do either would be an injustice, for one would lose the sense of variability the other exemplifies. One could eliminate the problem by renaming the grade *colonial nesters*, but by doing so one would lose more of the appreciation for diversity within the family.

The example may be an extreme one, but it does not depict a rare occurrence. Closely related species can have wide variations in any trait—Consider the greatly different social systems of the baboon species *Papio hamadryas* (one-male harem) and *Papio anubis* (multimale troop). And depending on one's definition of relatedness, one finds that within the primate superfamily Hominoidea, a wide variety of social organizations exist—from monogamous pairs to troop-living species (Eisenberg, Muckenhirn, & Rudran, 1972). Picking a representative would certainly be an impossible task. The only mechanism in the grade scheme for dealing with typologies of this sort is to make the grade ever more general. Far from being useful, grades then become arbitrary, broad, and meaningless.

Utility of Evolutionary Scales in Comparative Psychology

Another serious flaw in the Yarczower–Hazlett formulation is their almost complete inattention to behavior, even though their stated purpose was to examine behavioral evolution. Virtually all their examples come from anatomy and physiology—areas in which complexity can be measured relatively simply. But where behavior is concerned, complexity is an intractable concept. To continue a previous example, on the basis of sheer numbers, it might be concluded that a multimale troop's social structure is more complex than that of a one-male harem. Alternatively, one might argue that the loose aggregation of *P. hamadryas* baboons is actually more complex in that it is composed of highly discrete one-male units that manage to cooperate in foraging, traveling, and so on, with few overt interactions. Similarly, which is more complex, polygyny or polyandry? Is scent marking a territory more complex than vocally advertising that territory? In short, when considering behavior one is usually hard pressed to decide exactly how to rank order the candidates in terms of increasing complexity.

When faced with the difficult task of ranking several behaviors, one should be aware of the temptation to simply call the behavior found in the more recently evolved taxon the more complex. In our opinion, Yarczower and Hazlett may have fallen into this trap when they claimed that probability-maximizing, a strategy adopted by the rats in Bitterman's (1965) classic studies, is more complex and advanced than probability-matching, the strategy used by fish. We feel that a strong case can also be made for probability-matching being the more complex behavior. Maximization requires only a greater-than/less-than comparison; but in matching, the degree of difference between the two manipulanda is taken into account. Also, as Bitterman's data suggest, matchers adjust their response distributions very quickly following changes in reinforcement distribution, reflecting a sensitivity to environmental change exceeding that of the maximization strategy. The lesson of this example should be clear: One must not assume a priori that the more recently evolved taxon will necessarily exhibit the more complex form of the behavior.

Given that one assumes Yarczower and Hazlett's rationale for the development of grades and then constructs a series of grades based on some trait, one is left with the final question, What can be said about the results? Unfortunately, we feel the final answer is, Nothing. At best one arrives at the description of behavior in related animals (after arbitrarily defining *related* and toiling over choosing representative examples). At

worst, however, one does something more nefarious—One gives the impression that the grades represent a *scala naturae*. This impression arises from two points: first, that there is a rough correlation between complexity and evolutionary recency, which tends to clump "higher" animals in the more "improved" grades, and second, that the actual presentation of description in this form must have some underlying reason for existence other than description. In short, little is accomplished, except perhaps the generation of a lively debate over which grade is really the most improved. Indeed, once a scale has been developed, the only possible use that can be made of it (beyond the aforementioned descriptive function) is to make inferences that must employ adaptation of the particular organisms to their respective ecological niches.

We vigorously disagree with the statement (Yarczower & Hazlett, 1977, p. 1092) that the construction of a hierarchical progression of grades can have evolutionary significance beyond that of the study of adaptations. The source of our disagreement stems from the fact that characters exist as adaptations. To speak only of characters *in vacuo*, divorced of their adaptive significance, is meaningless in terms of evolution. Thus, to say that reptiles, although having "attained" the grade Amniota, have not attained the grade Homeothermy, "which reflects an improvement in the mechanism responsible for the regulation of body temperature" (Yarczower & Hazlett, 1977, p. 1096), is to say nothing of significance. The concept of not attaining this grade is meaningless, since selection pressures on reptiles are such that poikilothermy is generally favored.

In conclusion, we believe that evolutionary scales have no place in a modern comparative science of behavior. The idea of improvement smacks of anthropocentrism and is certainly arbitrary. These concepts are without value and may be seriously misleading. Scaling can only hinder interpretation of comparative psychologists' efforts by more traditional, evolution-oriented behaviorists at a time when these disciplines are reaching common grounds for interaction after having been polarized for so long at the extremes of the learned–instinct continuum.

In Defense of Anagenesis, Grades, and Evolutionary Scales

Matthew Yarczower and Bret S. Yarczower
Bryn Mawr College

We show that the first three criticisms by Capitanio and Leger of the Yarczower and Hazlett article are unfounded and that the fourth is premature: (a) Contemporary leaders in the study of evolution define anagenesis in the same way as did Yarczower and Hazlett; (b) their use of the term *evolutionary grade* was internally consistent and consistent with usage by Mayr, whom Capitanio and Leger cited as having used it differently; (c) classification of species into higher taxa does not represent "typological thinking"; and (d) although analyses by grades of social behaviors are more difficult than those of sensory systems, as was noted by Yarczower and Hazlett, it is premature to conclude that the effort will not bear fruit.

We answer in turn each of the four criticisms leveled at the Yarczower and Hazlett (1977) article and show that the first three are unfounded and that the fourth is premature.

1. *"Misconception of anagenesis."* Capitanio and Leger (1979) claimed that although at one time anagenesis meant what Yarczower and Hazlett claimed it to mean, it currently refers to any evolutionary change.

Gould (1976), a paleobiologist at Harvard's Museum of Comparative Zoology, has written about the concepts of anagenesis, evolutionary progress, and grades in a book that was received too late for the ideas contained within it to be incorporated into the Yarczower and Hazlett article. He wrote, "The standard evolution tree . . . leaves out evolutionary progress (or anagenesis) entirely . . . . Grades . . . are successive levels of organization defined as stages in the *improvement* of an organic design for some specified function" (p. 117; italics added). Or read what Jerison, author of *Evolution of the Brain and Intelligence* (1973), had to say about the terms *anagenesis* and *grades* in his address entitled "Smart Dinosaurs and Comparative Psychology" (Note 1). He said, "For an evolutionary analysis of intelligence, we might seek evidence of 'intellectual' *progress* from earlier to later species. This analysis is called 'anagenetic' and is about *progressive evolution*" (pp. 1–2; italics added). And again, "In anagenetic analysis the objective is to identify *grades* in evolution, recognizing the possibility of higher, or more advanced, grades on a particular dimension" (p. 2).

In fact, if one reads further in the source used by Capitanio and Leger to define anagenesis (Dobzhansky, Ayala, Stebbins, & Valentine, 1977) one reads, "Anagenetic episodes commonly create organisms with novel characters and abilities *beyond* those of their ancestors" (p. 236; italics added). And again, in describing the relationship among anagenesis, cladogenesis, and stasigenesis, anagenesis is defined as "evolutionary *advance* or change" (p. 236; italics added). Thus, the definition of anagenesis in the Yarczower and Hazlett article is one shared by leading contemporary students of evolution.

2. *"Inconsistencies in the use of the term* evolutionary grades." Capitanio and Leger's (1979) first criticism, although incorrect, at least is clear; the second is unclear. We believe there are two points they wished to make. They wrote that if "parallelism is

Requests for reprints should be sent to Matthew Yarczower, Department of Psychology, Bryn Mawr College, Bryn Mawr, Pennsylvania 19010.

taken to refer only to 'closely' related species, they must then consider the distinct probability that they were dealing with homologous traits—a task they explicitly wished to circumvent" (p. 877). What Yarczower and Hazlett (1977) wrote, in fact, was that "in the study of anagenesis it is important that the animals be related at least by parallel evolution" (p. 1090). It is puzzling that Capitanio and Leger read this and concluded that homologous traits were meant to be excluded from an anagenetic analysis. Animals must be related at least by parallel evolution, and obviously, direct descendancy or relationships underlying behavioral homologies satisfy the criterion of being related "at least by parallel evolution."

Capitanio and Leger also suggested that Yarczower and Hazlett's use of the term *evolutionary grade* differed from that of Mayr (1970) and Wilson (1975). Mayr (1963) wrote, "The felicitous term 'grade' was introduced into the evolutionary literature by Huxley . . . following Simpson . . . to designate 'a step of anagenetic advance, or unit of biological improvement'" (pp. 608–609). In a later abridged version of the same work, Mayr (1970) offered exactly the same sentence, but omitted Simpson's name. In any case, in both versions, Mayr then went on to note that "several *related* lines may reach the same adaptive or structural grade independently" (1963, p. 609; 1970, p. 365). Further, Mayr (1970) wrote that "Simpson in particular . . . has pointed out how rapidly a new type may reach a new phylogenetic 'grade,' but once this grade is reached the type remains essentially stable" (pp. 370–371; the 1963 version on p. 617 is almost identical). Mayr's discussion of grades relied heavily on Simpson's (1961) usage, as did Yarczower and Hazlett's (1977, pp. 1091–1092), and thus it should come as no surprise that usage of the term *evolutionary grade* by Mayr (1963, 1970) and by Yarczower and Hazlett does not differ and that no evidence to the contrary was presented by Capitanio and Leger. Wilson's (1975) suggestion "that phylogenetically remote lines can reach and pass through the same grades" (p. 25) does differ in principle from the suggestion of Yarczower and Hazlett (1977), as well as from that of Simpson (1961) and that of Mayr (1970).

3. *"Typological thinking."* Capitanio and Leger applied the concept of typology, or typological thinking, inappropriately. For its correct use, see Mayr (1963, 1969, 1970, 1976). We answer, however, the criticism raised by them. They seemed to object to the placing of two instances into a single class. They claimed that the uniqueness and individuality of each instance is lost when one notes the similarity between the two instances. Yet, surely statements about commonalities among instances are a goal of science. Indeed, when Capitanio and Leger labeled the gulls in their example as *kittiwakes,* they could very well have been accused of having lost an appreciation of the differences between Judy and Fred Kittiwake. Yarczower and Hazlett noted that inclusion in one grade did not mean that the same groups of animals would be placed together in other grades. The diversity among groups of animals indeed was recognized. But Capitanio and Leger appear to object to classification of species into higher taxa. If they do, then surely they must object to an important goal of the field of systematics. Mayr (1969) wrote that "each species may exist in numerous forms (sexes, ages, classes, seasonal forms, morphs, and other phena). It would be impossible to deal with this enormous diversity if it were not ordered and classified" (p. 1). And again, "One of the major preoccupations of systematics is to determine . . . what unique properties of every species and *higher taxon* are. Another is to determine what properties certain taxa have in common with each other" (p. 3; italics added).

4. *"Lack of utility of evolutionary scales."* This final charge reflects a number of misunderstandings by Capitanio and Leger as well as a legitimate challenge, one that Yarczower and Hazlett issued themselves. Capitanio and Leger (1979), in discussing social behavior, suggested that "one is usually hard pressed to decide exactly how to rank order the candidates in terms of increasing complexity" (p. 878). Yarczower and Hazlett (1977) stated explicitly that "it is more difficult to obtain agreement about what con-

stitutes improvement in social systems than about sensory systems. However, difficulty alone is not sufficient grounds for rejecting the notion of evolutionary scales" (p. 1096). Incidentally, Capitanio and Leger appear to treat increased complexity as synonymous with progressive improvement, but it should be noted that in their discussion of an example of progressive improvement in color vision, Yarczower and Hazlett never used the word *complexity*. This word was used in a brief review of the history of the concept of anagenesis. It is difficult to define improvement but not impossible. Consider an analysis of facial behavior. If facial movement is treated as the behavioral character to be subjected to an analysis by grades, then it is not unreasonable to assume that improvement is reflected in the increased ability to engage in greater varieties and intensities of facial behaviors. It is clear that the evolution of facial musculature is of prime importance in understanding the progressive improvement that seems to be reflected in the evolution of facial behavior (Chevalier-Skolnikoff, 1973; Huber, 1931/1972). The social significance of the evolution of facial musculature and the concomitant improvement in facial movements and facial behavior are considerable. The importance of research on facial behavior and facial expression (e.g., Ekman, 1973; Ekman & Friesen, 1976; Izard, 1971) for an understanding of a rich variety of social behavior provides some optimism that it may be possible to define improvement in systems relevant to social phenomena.

Capitanio and Leger (1979) concluded that Yarczower and Hazlett discussed "characters *in vacuo*, divorced of their adaptive significance" (p. 879). They came to this conclusion from a statement by Yarczower and Hazlett (1977) that "a hierarchical progression of grades . . . has evolution significance beyond that of the study of adaptations" (p. 1092). Even a casual reading of this statement does not lead to the conclusion that the adaptive significance of the grades is to be ignored. Yarczower and Hazlett discussed the differences among the goals of the study of behavioral homologies, adaptations, and grades, and they need not be repeated here.

A legitimate question raised by Capitanio and Leger asks whether analyses by grades can provide any interesting or important answers. They concluded that they cannot. This question cannot be treated in isolation from other attempts to understand the evolution of behavior. For example, there is a lively controversy about whether the search for behavioral homologies is likely to be a profitable one (e.g., Atz, 1970; Hailman, 1976; Hodos, 1976). Will the analyses of grades be profitable? Mayr (1976) stated, "The existence of minor and major grades is one of the most interesting phylogenetic phenomena, even though it is a phenomenon which we are still unable to understand adequately" (p. 450). And again, "To the evolutionary taxonomist the existence of grades seems often more significant and more meaningful biologically than the mere splitting of phyletic lines" (p. 451). Gould (1976) noted that

> lemur-monkey-ape-man is a caricature of primate phylogeny; once we are sure that the species we study are representative of their grade, this same sequence may well unravel the mysteries of neocortical function in successive levels of organization of the primate brain. . . . I do not think that analysis by grades is likely to be abandoned even in a pipedream world where phylogenies are laid out upon laboratory tables. (p. 121)

It may well turn out that analysis by grades will not bear fruit, but better that this be the result of recognizing, testing, and rejecting the potential value of analysis by grades than the result of ignorance about grades' existence.

Protecting the Overall Rate of Type I Errors for Pairwise Comparisons With an Omnibus Test Statistic

H. J. Keselman
University of Manitoba
Winnipeg, Canada

Paul A. Games
Pennsylvania State University

Joanne C. Rogan
University of Manitoba, Winnipeg, Canada

Two procedures for protecting the number of false rejections for a set of all possible pairwise comparisons were compared. The two-stage strategy of computing pairwise comparisons, conditional on a significant omnibus test, was compared with the multiple comparison strategy that sets a "familywise" critical value directly. The analysis of variance test, the Brown and Forsythe test, and the Welch omnibus test, as well as three procedures for assessing the significance of pairwise comparisons, were combined into nine two-stage testing strategies. The data from this study establish that the common strategy of following a significant analysis of variance F with Student's t tests on pairs of means results in a substantially inflated rate of Type I error when variances are heterogeneous. Type I error control, however, can be obtained with other two-stage procedures, and the authors tentatively consider the Welch F''–Welch t'' combination desirable. In addition, the two techniques for controlling Type I error do not substantially differ as much as might be expected; some two-stage procedures are comparable to simultaneous techniques.

Given K independent samples of size n_k, many experimenters are interested in testing the equality of the pairs of means. One can consider the complete set of means a family, in that if H_0, $\mu_1 = \mu_2 = \mu_k = , \ldots, = \mu_K$, is true, then it is also true that $\mu_k = \mu_{k'}$ for all possible pairs. The risk of making one or more Type I errors on the pairs is identified as the "familywise" risk of Type I error (FWI). This is contrasted with the risk of making a Type I error on a single contrast, which is labeled the per-comparison Type I error rate (PCI). Two general procedures can be used in this situation. A simultaneous multiple comparison procedure such as Tukey's (Note 1) wholly significant difference test compares all pairs using a critical value (CV) that controls FWI.

This research was supported in part by Canada Council Grant 451-77065 and in part by the Pennsylvania State University Computation Center.

Requests for reprints should be sent to H. J. Keselman, Department of Psychology, University of Manitoba, Winnipeg, Manitoba, Canada R3T 2N2.

The second, more likely used procedure is a two-stage strategy. The control of FWI is accomplished by an initial omnibus test such as the analysis of variance (ANOVA) F test. Only if this first stage is significant does the user proceed to test the pairs. Then the pairs can be tested by using a critical value that controls only PCI. Such a critical value is always smaller than the above FWI CV. Consequently, it automatically follows that if one reaches the second stage, the tests on pairs will have greater power than the tests on pairs that directly control FWI via a larger CV. However, since this second stage is equivalent to doing $K(K-1)/2$ pairs of t tests, the total risk of Type I error rises with K, so that only the first stage provides FWI control in this process. This procedure, commonly referred to as the protected least significant difference (LSD) technique, was introduced by Fisher (1949) and was recommended by Carmer and Swanson (1973) over most multiple comparison procedures.

Unfortunately, Carmer and Swanson used

only the omnibus ANOVA and investigated only the equal sample size and homogeneous variance condition in their study. The ANOVA is known to be sensitive when unequal sample sizes are combined with unequal population variances (Box, 1954), so that this omnibus test often does not provide acceptable control of FWI when sample sizes are not equal. However, two alternate omnibus tests for mean equality have been shown to be more robust than the ANOVA F (Brown & Forsythe, 1974; Kohr & Games, 1974).

The Brown and Forsythe test, like the ANOVA, uses just sample sizes in the numerator to weight means, whereas the multisample Welch (1951) test weights the means by sample variances as well as by sample sizes. However, both tests, rather than obtaining a CV based on the usual ANOVA error degrees of freedom (df), obtain a modified CV that is a function of sample variances and sizes. Consequently, either of these tests may provide the stable FWI control needed to make the two-stage procedure robust. However, Type I error control still may not be achieved when Student's t tests are used to assess the pairwise comparisons following a significant first-stage omnibus test, particularly when the omnibus test is the ANOVA; that is, prior literature (e.g., Box, 1954; Boneau, 1960) suggests that two-stage procedures using a pooled within-cell estimate of error variation in either stage should not maintain the Type I error rate at the significance level when variances are heterogeneous.

Type I error control may be achieved by adopting follow-up procedures that are intended to counteract the effects of variance heterogeneity. The contributions by Welch (1947) and Hochberg (1976) are applicable. The former technique uses the sample variances and sizes to obtain a modified CV, whereas by adopting Hochberg's work one uses a follow-up test statistic that has a nonpooled estimate of the standard error of the mean difference.

The present study, therefore, compared the rates of Type I error for nine LSD two-stage procedures to empirically verify in particular that the ANOVA F followed by Student's t sequence does not provide control of FWI and to find an improved two-stage strategy. To provide recommendations for controlling the overall rate of Type I error for a set of pairwise comparisons, we compare our results with simultaneous multiple comparison procedures.

Definition of Test Statistics

Let X_{ik} represent the ith observation in the kth group, where $i = 1, \ldots, n_k$, $k = 1, \ldots, K$ and $\sum n_k = N$. The X_{ik}s are independent normal variates with expected values μ_k and variances σ_k^2. The best linear unbiased estimates of μ_k, σ_k^2 and σ^2 are

$$\bar{X}_{.k} = \sum_i X_{ik}/n_k,$$

$$s_k^2 = \sum_i (X_{ik} - \bar{X}_{.k})^2/(n_k - 1),$$

$$MSW = \sum_{ik} (X_{ik} - \bar{X}_{.k})^2/(N - K),$$

respectively (MSW = mean square within groups).

The omnibus test statistics are as follows: For ANOVA F,

$$F = \frac{\sum_k n_k(X_{.k} - \bar{X}_{..})^2/(K-1)}{\sum_{ik} (X_{ik} - \bar{X}_{.k})^2/(N-K)},$$

where $\bar{X}_{..} = \sum_k n_k\bar{X}_{.k}/N$. When the population variances are homogeneous, F is distributed as a F variable with $K-1$ and $N-K$ degrees of freedom. For Brown and Forsythe's (1974) F^*,

$$F^* = \frac{\sum_k n_k(\bar{X}_{.k} - \bar{X}_{..})^2}{\sum_k (1 - n_k/N)s_k^2},$$

where F^* is approximately distributed as F with $K-1$ and f degrees of freedom and f is obtained with the Satterthwaite (1941) approximation,

$$1/f = \sum_k c_k^2/(n_k - 1);$$

$$c_k = (1 - n_k/N)s_k^2/[\sum_k (1 - n_k/N)s_k^2].$$

For Welch's (1951) F'',

$$F'' = [\sum^K w_k (\bar{X}_{.k} - \bar{\bar{X}}_{.})^2/(K-1)]/$$
$$1 + [2(K-2)/(K^2-1)]$$
$$\times \{\sum^K [1/(n_k - 1)](1 - w_k/\sum w_k)^2\},$$

where $w_k = n_k/s_k^2$ and

$$\bar{\bar{X}}. = \sum^{K} w_k \bar{X}._k / \sum^{K} w_k.$$

The Welch statistic is approximately distributed as an F variable with $K-1$ and

$$\nu_w = (K^2 - 1)/\{3 \sum [1/(n_k - 1)] \times (1 - w_k/\sum w_k)^2\}$$

degrees of freedom.

The pairwise comparisons can be assessed for statistical significance with the statistic

$$t = (\bar{X}._k - \bar{X}._{k'})/[\text{est}\ (\sigma_k^2/n_k + \sigma_{k'}^2/n_{k'})]^{\frac{1}{2}}$$

to test the null hypothesis, $\mu_k - \mu_{k'} = 0$ $(k \neq k')$. The t designation is not meant to imply that this statistic fits Student's t distribution, particularly under heterogeneous variances.

The estimated standard errors of the mean differences for the pairwise tests are (a) Student's pooled denominator,

$$(MSW/n_k + MSW/n_{k'})^{\frac{1}{2}};$$

(b) Hochberg's (1976) nonpooled denominator,

$$[2 \max (s_k^2/n_k, s_{k'}^2/n_{k'})]^{\frac{1}{2}};$$

and (c) the Behrens (1929)–Fisher (1935) denominator (used with a modified CV),

$$(s_k^2/n_k + s_{k'}^2/n_{k'})^{\frac{1}{2}}.$$

The three forms of t use a $t_{(\alpha/2)}$ CV. The error df for Student's and Hochberg's ts equals $N - K$. The variable error $df(\nu_w)$ for the third denominator is Welch's (1947) solution for ν_w, where

$$\nu_w = \frac{(s_k^2/n_k + s_{k'}^2/n_{k'})^2}{\dfrac{(s_k^2/n_k)^2}{n_k - 1} + \dfrac{(s_{k'}^2/n_{k'})^2}{n_{k'} - 1}}.$$

Methods of the Simulation Study

Pseudorandom normal observations of sizes 29, 41, 65, and 89 were obtained from the Marsaglia, MacLaren, and Bray (1964) random number generator.[1] An omnibus test statistic was then computed on the data. If the observed value of the omnibus test exceeded a 5% critical value based on 3 and error df the FORTRAN program was used to compute the six pairwise comparisons. This was repeated until 1,000 different significant results had been obtained on the omnibus tests. The average of the six per-comparison rates of Type I error (the average PCI) was then obtained by dividing the total number of false rejections by 6,000 (6 comparisons × 1,000 simulations).

If the observed value of the omnibus test did not exceed its critical value, the computer program was set up to return to the random number generator. For normally distributed observations with means of zero and a common variance of one, approximately 20,000 calls to the generator are necessary to obtain 1,000 significant omnibus tests for a 5% level of significance. To optimize programming efficiency, each omnibus-to-pairwise-comparisons combination was run separately. However, the starting numbers for the random number generator were kept the same for each combination, and consequently each of the omnibus tests started with the identical set of data.

A heterogeneous variance condition was also investigated. The unequal variances (.104, .790, .810, and 2.296) were inversely paired with the unequal sample sizes (i.e., smallest σ_k^2 with largest n_k and largest σ_k^2 with smallest n_k). This particular type of pairing was chosen because it delineates the case in which the rates of Type I error are inflated in tests using *MSW*.

Results and Discussion

Table 1 presents the results of the simulation study. The FWI values associated with each omnibus test are the probabilities that the omnibus test will yield a significant result and that the pairwise tests using PCI CVs will result in at least one significant pair. Since the latter usually happens whenever the omnibus test is significant, the FWI values in each of these columns are basically the same. Clearly, the major determinants of these FWI values are the characteristics of the omnibus tests themselves. The average PCIs are the average values of the per-comparison rates of Type I errors on the six comparisons of each experiment, given that a significant omnibus test was obtained; this is a conditional probability.

Looking at the top set of values in Table 1 under the homogeneous variance condition, one sees that all of the tests are very similar and perform about as expected when this major assumption has been met. The PCI averages are higher than .05 because they are conditional probabilities (which were computed here only when the sample means were sufficiently divergent to yield a significant omnibus test). In summary, the values in the upper section of the table suggest that any of

the omnibus tests can be used as the first step in the two-stage procedure when one has homogeneous variances.

The values in the lower section of Table 1 indicate that the ANOVA F is not to be trusted as the first stage when variances are heterogeneous and sample sizes are unequal. The FWI values are substantially above .05, except when the ANOVA is followed by Hochberg's (1976) conservative test. Probably the most commonly used technique is to calculate an ANOVA F as the first step and then follow this by Student's t tests if the F is significant. It is disturbing to find that under the heterogeneous variances condition with nominal alphas of .05, the FWI value is about .18 and that given a significant F, the mean probability of a Type I error in the comparisons that follow is .46.

For the unequal sample size–unequal variance case, the other two omnibus tests provide reasonable control of FWI, with the Welch (1951) F'' being slightly superior to the Brown and Forsythe (1974) F^*. However, although either is an improvement over the ANOVA F, it would be a mistake to follow either of these omnibus tests with a follow-up test that made use of MSW, since the standard errors based on this value would be inappropriate for various pairwise comparisons of the means (Games & Howell, 1976, p. 119). Thus, the choice for a follow-up test is limited to the Welch t'' (1947) or the Hochberg (1976) t procedures. All LSDs using the Hochberg t effectively controlled the rate of Type I error. However, the rates were conservative when the omnibus test used was F^* or F''. Because of this conservativeness we would expect these two LSDs to be relatively less powerful. The Welch F''–Welch t'' LSD also provided Type I control, but was not conservative and consequently should be relatively more powerful. However, the F^*–Welch t'' LSD proved to be slightly liberal and can be discounted if the user wants to maintain the number of Type I errors at or below the significance level.

Though not presented here, Type I error rates per family were collected to compare the Welch LSD(F''–t'') and simultaneous multiple comparison approaches.[2] Interestingly, the per-family rates were not very disparate. Consequently, though our preference is for the simultaneous multiple comparison

[2] The per-family Type I error rate is equal to the number of Type I errors made on the 6,000 comparisons (after a significant omnibus test) divided by the total number of families, or, here, by experiments run in the simulation (Miller, 1966, p. 5). The rates for the multiple comparison procedures (Tukey's, Note 1, procedure using the Welch, 1947, CV as suggested by Games & Howell, 1976) were obtained in another simulation study.

approach in testing pairwise comparisons, the data indicate that some two-stage least significant difference procedures can indeed provide Type I error control.

UBLISHED BIMONTHLY BY THE AMERICAN PSYCHOLOGICAL ASSOCIATION
ISSN 0033-2909

R. J. Herrnstein, *Editor, Harvard University*

Gene V Glass, *Associate Editor, University of Colorado*

Susan Herrnstein, *Assistant to the Editor*

The *Psychological Bulletin* publishes evaluative reviews and interpretations of substantive and methodological issues in the psychological research literature. The Journal reports original research only when it illustrates some methodological problem or issue. Discussions of methodological issues should be aimed at the solution of some particular research problem on psychology, but should be of sufficient breadth to interest a wide readership among psychologists; articles of a more specialized nature can be directed to the various statistical, psychometric, and methodological journals. The *Bulletin* does not publish original theoretical articles; these should be submitted to the *Psychological Review*.

Abstracts: All articles must be preceded by an abstract of 100–175 words. Detailed instructions for preparation of abstracts appear in the *Publication Manual of the American Psychological Association* (2nd ed.), or they may be obtained from the Editor or from APA Central Office.

Blind review: Because reviewers have agreed to participate in a blind reviewing system, authors submitting manuscripts are requested to include with each copy of the manuscript a cover sheet, which shows the title of the manuscript, the name of the author or authors, the author's institutional affiliation, and the date the manuscript is submitted. The first page of the manuscript should omit the author's name and affiliation but should include the title of the manuscript and the date it is submitted. Footnotes containing information pertaining to the author's identity or affiliation should be on separate pages. Every effort should be made to see that the manuscript itself contains no clues to the author's identity.

Manuscripts: Submit manuscripts in triplicate to the Editor, R. J. Herrnstein, *Psychological Bulletin,* Harvard University, 33 Kirkland Street, Cambridge, Massachusetts 02138, according to instructions provided below.

Instructions to Authors: Authors should follow the directions given in the *Publication Manual of the American Psychological Association* (2nd ed.). Instructions on tables, figures, references, metrics, and typing (all copy must be double-spaced) appear in the Manual. Authors are requested to refer to the "Guidelines for Nonsexist Language in APA Journals" (Publication Manual Change Sheet 2, *American Psychologist,* June 1977, pp. 487–494) before submitting manuscripts to this journal. All manuscripts should be submitted in triplicate and all copies should be clearly readable, and on paper of good quality. Dittoed copies are not acceptable and will not be considered. Authors are cautioned to carefully check the typing of the final copy and to retain a copy of the manuscript to guard against loss in the mail.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $40 domestic, $42 foreign, $7 single issue. APA member rate: $15. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Dept., APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published bimonthly (beginning in January) in one volume per year by the American Psychological Association, Inc., 1400 North Uhle Street, Arlington, Va. 22201. Printed in the U.S.A. Second-class postage paid at Arlington, Va., and at additional mailing offices.

Human Spatial Abilities: Psychometric Studies and Environmental, Genetic, Hormonal, and Neurological Influences

Mark G. McGee
Texas A & M University

The spatial abilities literature is reviewed. Psychometric consideration encompasses both factor analytic studies that conclusively demonstrate the existence of at least two Spatial factors—Visualization and Orientation—and predictive validity studies that argue for these factors' social relevance. Sex differences in various aspects of perceptual-cognitive functioning (e.g., mathematics, field independence) are interpreted as a secondary consequence of differences with respect to spatial visualization and spatial orientation abilities. Sources of variation in performance on spatial tests including environmental, genetic, hormonal, and neurological are considered, with special emphasis on age and sex differences. Evidence that variation in spatial test scores is to some degree heritable remains positive; however, the X-linked recessive gene hypothesis that has served as a tentative explanation for sex differences in spatial abilities and for the mode of genetic transmission is not supported strongly in recent studies. Neurological studies showing variations in the lateral organization of the human brain provide experimental evidence for a structural source of the variation in spatial abilities, and this evidence is reviewed as it relates to human handedness and cerebral bilateralization for spatial and linguistic functions.

The purpose of this article is threefold: (a) to summarize psychometric studies of human spatial abilities, (b) to examine the consistencies and disagreements in relation to the hypothesis that sex differences in various aspects of perceptual-cognitive functioning (e.g., mathematics, field dependence–field independence) are a secondary consequence of differences with respect to spatial visualization and spatial orientation abilities, and (c) to review the literature with reference to environmental, genetic, hormonal, and neurological influences that interact in producing individual variation in spatial test scores.

Psychometric Studies

Early Factor Analytic Studies

Historically, the identification of the Spatial factor has roots in the study of mechani-

cal aptitude (Cox, 1928; Paterson, Elliott, Anderson, Toops, & Heidbreder, 1930; Smith, 1964; Stenquist, 1922) and practical ability (W. P. Alexander, 1935; Kohs, 1923; McFarlane, 1925). In one of the earliest studies of "practical ability," McFarlane found evidence for a group factor over and above general intelligence (*g*). She described individuals in possession of the practical ability underlying this factor as being adept at judging concrete spatial relations.

Since 1925, numerous factor analytical studies have yielded a Spatial factor mathematically distinct from verbal ability. Kelley (1928) identified a Spatial factor and described it as the mental manipulation of shapes. Brown and Stephenson (1933) found that two tests in particular had substantial loadings on their Spatial factor: fitting shapes, which is a paper-form-board test, and a test of dot perception. Koussy (1935) identified a group factor (K) among 28 tests administered, and he concluded from introspective reports by participants in the study that the mental processes active in the solution of problems involving the K factor were characterized by the "ability to obtain and the facility to utilize, spatial imagery" (p. 86). A similar conclusion was reached independently by Smith (1938). Murphy (1936) factor analyzed scores from numerous verbal, nonverbal, and mechanical tests and concluded that mechanical ability included two factors: Speed of Eye–Hand Coordination and Mental Manipulation of Spatial Relations. Clarke (1936) reported the Spatial factor loadings of spatial and verbal tests to be inversely related among girls ranging in age from 12 to 15 years, a relationship that has been replicated with males as well as females (Andrew, 1937a, 1937b; Broverman & Klaiber, 1969; Emmett, 1949; Estes, 1942; Heston, 1943; Morris, 1939; Slater, 1940; Smith, 1938; Swineford, 1948; Thurstone, 1944, 1947; Wittenborn, 1945). This relationship is less likely to obtain for spatial-performance tests highly correlated with general intelligence (e.g., the Block Design subtest of the Wechsler IQ scales, or the Kohs Block Design Test that correlates .80 with Binet IQ scores, Kohs, 1923).

Recent Factor Analytic Studies

Several recent studies have discussed the presence of a Spatial factor among batteries of tests administered (DeFries et al., 1974; DeFries et al., 1976; Goldberg & Meredith, 1975; Gough & Olton, 1972; Hakstian & Cattell, 1974; Yen, 1975; Zonderman, Vandenberg, Spuhler, & Fain, 1977), and others have shown a Spatial factor that reliably appears in cognitive test scores of different racial, ethnic, and socioeconomic (SES) groups. Michael (1949), for instance, found a generally similar factor structure among ability measures on black and white Air Force cadets. Flaugher and Rock (1972) found similar factor structures in a battery of 9 cognitive measures administered to black, white, Mexican American, and Oriental American high school males. Among Americans of European and Japanese ancestry, DeFries et al. (1974) found four factors in the 15 cognitive tests administered: Spatial Visualization, Verbal, Memory, and Perceptual Speed. Humphreys and Taber (1973) found six factors in 21 ability measures from the Project TALENT test battery, and the factor structure was similar for 9th-grade boys in the top and bottom quartiles on SES. Backman (1971, 1972) compared 12th-grade Jewish and non-Jewish whites and Oriental Americans in performance on six mental ability factors—Spatial, Verbal, English Language, Math, Perceptual Speed, and Memory—and found ethnicity and SES to have much less influence on the ability profile than did sex. Similar subtest intercorrelation patterns have been reported by Nichols (1971) and Scarr-Salapatek (1971) for U.S. whites and blacks. These studies all agree with the suggestion "that underlying dimensions of ability vary little if at all across U.S. racial-ethnic groups" (Loehlin, Lindzey, & Spuhler, 1975, p. 179).

An equally important emphasis of recent factor analytic research has been that of disentangling various subabilities that characterize the Spatial factor. The available evidence conclusively demonstrates the existence of at least two Spatial factors: Visualization and Orientation. Table 1 presents a summary of Spatial Visualization and Spatial

Orientation factor symbols and descriptions. Although factor names and symbols differ in the four studies cited in Table 1, factor descriptions are strikingly similar.

The first clear evidence for the existence of spatial abilities resulted from an impressive series of factor analytic studies initiated by L. G. Humphreys of the Army Air Force

Table 1
Summary of Spatial Visualization and Spatial Orientation Factor Symbols and Descriptions

	Spatial visualization factor		Spatial orientation factor	
Investigator	Symbol	Description	Symbol	Description
Guilford and Lacey, (1947)	V_z	An ability to imagine the rotation of depicted objects, the folding or unfolding of flat patterns, the relative changes of position of objects in space, the motion of machinery. This visualization factor is strongest in tests that present a stimulus pictorially and in which some manipulation or transformation to another visual arrangement is involved.	SR	An ability to determine relationships between different spatially arranged stimuli and responses and the comprehension of the arrangement of elements within a visual stimulus pattern.
Thurstone (Note 1)	S_2	An ability to visualize a configuration in which there is movement or displacement among the internal parts of the configuration.	S_1	An ability to recognize the identity of an object when it is seen from different angles or an ability to visualize a rigid configuration when it is moved into different positions.
			S_3	An ability to think about those spatial relations in which the body orientation of the observer is an essential part of the problem.
French (1951)	V_i	An ability to comprehend imaginary movements in three-dimensional space or the ability to manipulate objects in the imagination.	S	An ability to perceive spatial patterns accurately and to compare them with each other.
			SO	An ability to remain unconfused by the varying orientations in which a spatial pattern may be presented. Dimensionality is less important to the factor than the rotational position of presentations.
Ekstrom, French, and Harman (Note 3)	VZ	An ability to manipulate or transform the image of spatial patterns into other arrangements; requires either the mental restructuring of a figure into components for manipulation or the mental rotation of a spatial configuration in short term memory, and it requires performance of serial operations, perhaps involving an analytic strategy.	S	An ability to perceive spatial patterns or to maintain orientation with respect to objects in space; requires that a figure be perceived as a whole.

Note. Adapted from Michael, Guilford, Fruchter, and Zimmerman (1957, Table 1, p. 188).

(AAF) (Guilford & Lacey, 1947; Guilford & Zimmerman, 1947). The results, based on repeated analyses from AAF tests administered to thousands of military personnel, indicated two Spatial factors: Spatial Visualization (V_z) and Spatial Relations (SR). Visualization was described as the ability to imagine the rotation of depicted objects, the folding or unfolding of flat patterns, the relative changes of position of objects in space, or the motion of machinery. Spatial Relations was described as comprehension of the arrangement of elements within a visual stimulus pattern.

Thurstone (1938) had isolated a Space factor that he designated as a facility in spatial and visual imagery, but it was not until 1950, when he found several primary abilities in visual thinking and related three of these to visual orientation in space, that the differentiation between them became better understood. The first of these three factors was designated S_1 (Thurstone, Note 1). He asserted that it represented the ability to recognize the identity of an object when it was seen from different angles. This factor was also characterized by the ability to visualize a rigid configuration when it was moved into different positions. The second factor identified by Thurstone (Note 1), S_2, was said to represent the ability to imagine movement or internal displacement among the parts of a total configuration. Thurstone's distinction between abilities to imagine transformation of wholes (S_1) versus parts (S_2) is unique and needs verification. The third factor (S_3) was identified by Thurstone as the ability to think about those spatial relations in which the body orientation of the observer is an essential part of the problem.

In 1951, French identified a Visualization factor (V_i), described as the ability to mentally manipulate three-dimensional objects, and an Orientation factor (SO), described as an ability to remain unconfused by the varying orientations in which a spatial pattern may be presented.

French, Ekstrom, and Price (Note 2) described V_z as an ability to manipulate or transform the image of spatial patterns into other visual arrangements and spatial orientation as an ability to perceive spatial patterns or maintain orientation with respect to objects in space. More recently, Ekstrom, French, and Harman (Note 3), in their manual for Kit of Factor-Referenced Cognitive Tests, have suggested that visualization ability requires that a figure be mentally restructured into components for manipulation, whereas the whole figure is manipulated in spatial orientation. Both spatial orientation and visualization require short term visual memory. Orientation requires only mental rotation of the configuration; however, visualization, according to this more recent definition, requires both rotation and the performance of serial operations. The requirement that a figure is perceived as a whole in spatial orientation but must be mentally restructured into components for manipulation in visualization (Ekstrom et al., Note 3) is reminiscent of Thurstone's (Note 1) distinction between abilities to imagine transformation of wholes (S_1) and parts (S_2).

Corroborative evidence for the existence of at least two Spatial factors has been provided. Guilford, Fruchter, and Zimmerman (1952), for example, found 12 factors in a test battery of 46 tests (including a Spatial Relations and a Visualization factor). The Visualization factor was represented as an ability to mentally manipulate elements of a pattern, and the Orientation factor was represented as an ability to determine spatial orientation with respect to one's body.

Summary

Factor analytic studies of the Spatial factor began with the study of practical and mechanical ability during the mid-1920s. Some investigators have found evidence for distinct factors of practical and mechanical ability, in addition to a Spatial factor; others have refuted this distinction (Dempster, 1948; Leff, 1949; Price, 1940; Slater, 1940; Watts, 1953; Williams, 1948). Although the debate over the existence versus nonexistence of a Spatial factor characterizes much of the literature prior to 1930, a plethora of factor studies since that date have provided strong and consistent support for the existence of two distinct spatial abilities: visualization and orientation.

As for visualization, the S_2 factor proposed by Thurstone (Note 1) is similar to the V_i factor proposed by French (1951), the V_z factor reported by the AAF researchers (Guilford & Lacey, 1947), and the V_z factor described by Ekstrom et al. (Note 3). All involve the ability to mentally manipulate, rotate, twist, or invert a pictorially presented stimulus object. The underlying ability seems to involve a process of recognition, retention, and recall of a configuration in which there is movement among the internal parts of the configuration (S_2) or the recognition, retention, and recall of an object manipulated in three-dimensional space (V_i) or which involves the folding or unfolding of flat patterns (V_z). The Spatial Visualization Test of the French et al. (Note 2) Kit of Reference Tests of Cognitive Factors, for example, requires the examinee to mentally fold and unfold a piece of paper and choose the alternative that represents the paper after it has been unfolded. The Guilford-Zimmerman (1953) Visualization Test consists of a picture of an alarm clock and a sphere with directional arrows, and the examinee is required to visualize the rotation of the clock as it is moved into different positions according to the directions of the arrows.

As for spatial orientation, the S_1 and S_3 factors proposed by Thurstone (Note 1), the SO factor proposed by French (1951), the SR factor proposed by Guilford and Lacey (1947), and the SO and S factors described by Ekstrom et al. (Note 3) are similar. All involve the comprehension of the arrangement of elements within a visual stimulus pattern and the aptitude to remain unconfused by the changing orientation in which a spatial configuration may be presented. The Spatial Orientation Test of the French et al. (Note 2) Kit of Reference Tests of Cognitive Factors requires the examinee to compare cubical blocks and indicate whether they are the same or different according to symbols written on their faces. The Guilford-Zimmerman (1953) Spatial Orientation Test requires the examinee to imagine riding in a boat whose prow is always visible in the foreground of the pictures that comprise each item and to choose among the alternative new directions of the boat.

Regarding factor analytic studies of spatial abilities in general, some qualifications need to be made. First, after 70 years of psychometric research, there is still vast disagreement about just how best to classify standard tests of spatial abilities. Further factor analytic studies are indicated. Second, the influence of test-item difficulty on factor structure needs to be further explored. Myers' (Note 4) suggestion that visualization test items are usually more difficult than orientation items has been supported (Zimmerman, 1954a, 1954b), although not replicated. Third, spatial tests consisting of both two- and three-dimensional items are used with equal frequency, but little is known about how dimensionality contributes to the factor structure of spatial tests. Fourth, studies showing positive correlations between tests of spatial visualization and orientation (Borich & Bauman, 1972; Goldberg & Meredith, 1975; Karlins, Schuerkoff, & Kaplan, 1969; Roff, 1952; Yen, 1975) illustrate the need for further factor analytic research to clarify the specificity of the Visualization and Orientation factors.

Predictive Validity Studies

Information from predictive validity studies reinforces our judgment concerning the practical use of visualization and orientation abilities and proves their social significance. Historically, predictive validity has been important in the selection of candidates to fill openings in industry, colleges, and the armed forces. Predictive validity is at issue when the purpose of an instrument is to estimate some important form of behavior (Nunnally, 1978). The degree of relationship between an instrument and its criterion indicates the instrument's predictive validity. The use of tests to predict success in school is a widely accepted practice, and the educational institution beyond the elementary school level that does not use a standardized testing procedure in its evaluation of incoming students is now the exception.

To what practical use can we direct our knowledge of human spatial abilities? What are the implications of this knowledge for use in everyday life? And to what extent is

this knowledge useful in predicting socially significant and relevant behavior? We have two lines of evidence directly relevant to these issues: first, the literature regarding the value of spatial tests for selecting workers for industrial jobs and predicting job performance and, second, the literature regarding the use of spatial tests for the prediction of success in vocational–technical training programs.

Selecting workers for industrial jobs and predicting job performance. The value of spatial tests for use in making personnel selection decisions has been well documented elsewhere. Ghiselli (1966, 1973), for example, has summarized much of the literature relevant to the predictive validity question of occupational aptitude tests. The U.S. Employment Service (1957) has listed those occupations requiring a high level of spatial ability. Four job categories—engineering, science, drafting, and designing—account for nearly 85% of all jobs listed.

Predicting success in vocational–technical training programs. The earliest evidence for the prediction of success in school work with a test specifically designed to measure spatial ability was provided by O'Connor (cited in Smith, 1964). Using the O'Connor Wiggly Block Test, he found predictive validities of .62 and .42 for shop grades in two groups of vocational school boys.

Paterson et al. (1930), in their massive investigation of mechanical ability, found spatial tests to be especially useful in predicting success in various junior high school and technical school courses. The spatial test battery (consisting of several tests including the Minnesota Paper Form Board Test, the Link Spatial Relations, and the Packing Blocks Tests) yielded a multiple correlation of .60 with success in shop courses and correlated .07 with intelligence.

Holliday (1940) administered a battery of spatial tests to several groups of trade school apprentices, engineer apprentices, and shop students. The verbal test administered correlated .07 with proficiency in technical drawing, whereas the corresponding correlation of the spatial battery was .66. In a subsequent investigation, Holliday (1943) administered a series of spatial, mechanical, and verbal tests to several groups of toolmakers and engineering and trade apprentices. Again it was found that the spatial tests yielded higher correlations with mechanical drawing than did the verbal tests administered. Slater (1941) conducted a validity study in which he used seven spatial tests in addition to a test of verbal ability to predict criterion estimates of engineering drawing ability and general apprenticeship ability. Drawing ability correlated .41 with composite scores on the spatial tests but only .26 with verbal ability. Shuttleworth (1942) found that tests of spatial ability showed higher correlations with grades obtained in junior technical school than tests of verbal and mechanical ability. Although the correlation between grades and the verbal test administered was only .20, the corresponding correlation for the Space Perception, Memory for Design, and Form Relations Tests were .46, .45, and .44, respectively. Hunter (1945) used the Minnesota Paper Form Board and the Otis Intelligence Test (Form B) among other tests in predicting course success for sophomore and junior machine shop students. Correlations against this criterion were .45 for the spatial test and .28 for the intelligence test. Smith (1948) administered 11 tests to first- and second-year pupils in a Scottish secondary school. The spatial battery included tests of area discrimination, completion, fitting shapes, form equations, classification, form-figure analogies, form recognition, pattern perception, and drawing. The Otis Intelligence Test (Form B) was also used. The spatial test battery was predictive of success in engineering drawing ($r = .66$) and art ($r = .39$). Correlations between grades in these two subjects and the Otis Intelligence Test were $-.07$ and .19, respectively.

Two validity studies reported by Smith (1964), corroborating the results of those presented above, were conducted by Knight (1949) and by Oxlade (1951). Knight reported results from a follow-up study of Middlesex Junior Technical School entrance examinees to determine the validity of spatial tests in predicting successful completion of the program. The battery of tests administered included a form relations test, a

memory-for-designs test, and a space perception test. Headmaster's ratings were also obtained. The criteria included performance in the program at the end of the first and second years. Correlations between predictor and criterion variables demonstrated the superiority of spatial tests over headmaster's ratings for selecting candidates. In the first year, the predictive value of headmaster's ratings and selection tests was similar, but, as the course became more advanced and technical in its second year, the predictive value of the selection tests became greater, whereas that of the headmaster's ratings decreased. Martin (1951) found that a spatial relations test predicted shop achievement and classroom grades among 45 auto mechanics in a California technical school. And in a related study, Hunt (1973) demonstrated the usefulness of a spatial test in predicting course achievement in a computational science curriculum.

Smith (1964) reported a follow-up study of pupils selected for technical education in which the major objective was to assess the predictive validity of various selection tests, including tests of spatial and verbal ability, against criteria of success in technical courses in a secondary technical school. Data were collected on students in a number of technical courses at 3 years after and at 5 years after the original selection examination. Both spatial tests that were used showed substantial correlations with criterion examination scores in all technical courses. The most highly significant regression coefficients for the two spatial tests tended to be in the areas of metalwork, woodwork, handicraft, and drawing (geometrical, building, and engineering). In contrast, the verbal reasoning test that was used showed low validity for the prediction of success in these same areas. Similar results had been provided from two previously conducted validity studies. Holzinger and Swineford (1946) examined the predictive validity of a battery of spatial tests with grades in various school courses and found that test scores correlated .002 with English, −.003 with biology, and −.06 with foreign language but .23 with plane geometry, .46 with shops and crafts, and .69 with drawing. The spatial tests included in the battery were of visual imagery, cubes, punched holes, figures, form relations, pattern perception, and drawings.

In related studies the predictive validity of spatial orientation and spatial visualization tests has been demonstrated. Hills (1957), for example, reported a validation study on the relationship between several measures of aptitude and success in college mathematics. The Spatial Visualization and Spatial Orientation Tests (Guilford & Lacey, 1947) were among the best predictors of mathematical grades, showing higher validity coefficients than the verbal tests used. Karlins et al. (1969) investigated cognitive factors relating to architectual creativity among graduating achitecture students and found a significant correlation of .49 between scores on Thurstone's Cubes Test (a measure of spatial orientation, Thurstone, Note 1) and quality of independent work completed. And the space subtest of the Differential Aptitude Test battery (Bennett, Seashore, & Wesman, 1974) is predictive of drafting ($r = .42$), shop mechanics ($r = .47$), and watch repair ($r = .69$), none of which is well predicted by verbal tests.

Relationship Between Spatial Abilities and Various Perceptual-Cognitive Tasks

Differential psychologists have been interested in spatial visualization and orientation because male superiority on tasks requiring these abilities is among the most persistent of individual differences in all the abilities literature (Anastasi, 1958; Buffery & Gray, 1972; Garai & Scheinfeld, 1968; Harris, 1978; Maccoby & Jacklin, 1974; McGee, 1977; O'Connor, 1943; Sherman, 1971; Smith, 1964; Tyler, 1965).

The widely documented sex difference on tests of spatial visualization and spatial orientation as well as on numerous tasks requiring these abilities does not reliably appear until puberty (Drew, 1944; Emmett, 1949; Fruchter, 1954; Gardner, Jackson, & Messick, 1960; Harris, 1978; Maccoby, 1966; Slater, 1941; Witkin et al., 1954). However, in studies in which differences have been reported in younger samples, boys typically showed superiority in performance (for

reviews, see Harris, 1978; Maccoby & Jacklin, 1974; Smith, 1964), which is particularly puzzling in light of the general maturational advantage in physical and cognitive development enjoyed by girls (Garai & Scheinfeld, 1968; Maccoby & Jacklin, 1974; Money & Ehrhardt, 1972; Waber, 1976, 1977).

In this section we examine the consistencies and disagreements in relation to the hypothesis that sex differences in various aspects of perceptual-cognitive functioning are a secondary consequence of differences with respect to spatial visualization and spatial orientation abilities.

Visualization Ability

Recall that spatial visualization involves the ability to mentally rotate, manipulate, and twist two- and three-dimensional stimulus objects. It is tempting to consider visualization as fundamental to good performance in various areas of mental functioning. Two areas are considered below: imagery and mathematical ability.

Imagery. Galton's (1880, 1883) pioneering work on individual differences in imagery led the way for researchers who have since been intermittently interested in the issue. The study of mental transformations of spatial images is returning to popularity in psychology and represents an attempt to examine the "major representational alternative" to language (Neimark & Santa, 1975) to more fully understand the mental processes involved in the solution of tasks that are difficult to solve by verbally mediated processes. For reviews, see Neimark & Santa, 1975; Pylyshyn, 1973; Lane, Note 5).

The empirical study of imagery has emphasized the measurement of imagery vividness and imagery control (Betts, 1909; Costello, 1957; Galton, 1880, 1883; Gordon, 1949; Marks, 1972; Richardson, 1969, 1972; Sheehan, 1967a, 1967b). It has been suggested (Richardson, 1972) that spatial manipulation involves imagery control and that imagery vividness and control may be related to individual differences in performance on tests of spatial ability. Those who lack control over their imagery have been described by Galton (1883) as having "difficulty in shifting their mental view of an object and examining it at pleasure in different positions" (p. 75). As noted by Koussy (1935), solving problems on spatial tests requires mental imagery and the ability to obtain and the facility to use visual spatial imagery. The role played by visual imagery in tests of spatial visualizing ability is unclear, however.

Although no studies have examined the relationship between imagery vividness, imagery control, and performance on tests of spatial ability, the work by Shepard and his associates on mental transformation of visual images has gained considerable attention. They have shown that the reaction time required for performing an instructed transformation is a linearly increasing function of the number of rotations or foldings required for determining whether two differently oriented objects have the same or different shapes (Shepard & Metzler, 1971) and for determining whether arrows on two sides will meet when a flat six-sided figure is folded into a cube (Shepard & Feng, 1972). This research has advanced our understanding of the nature of the underlying mental process involved in the solution of spatial visualization tasks such as those that appear on paper-folding and surface development tests of spatial ability. Further, it suggests the principle of "second-order isomorphism" (Shepard & Chipman, 1970), meaning that the events occurring during "imagining" of an external process (e.g., paper folding) are similar to the events occurring during the "perceiving" of an external process. The orderly relationship between (a) time required to recognize that two-perspective drawings portray objects of the same three-dimensional shape and (b) the angular differences in the portrayed orientations of the two objects (Shepard & Metzler, 1971) implies that while one is in the course of imagining the external process, one passes through an orderly set of internal states of special relation to the successive states of the external process (Shepard & Feng, 1972). Metzler and Shepard (1974) and Cooper and Shepard (1975) have described experi-

ments with college age males and females that confirm their earlier reports. No systematic attempt to examine sex differences has been made, although the slope of the reaction time functions tended to be higher for females than males (Metzler & Shepard, 1974), indicating that males require less time than females to solve Shepard's mental transformation tasks.

Mathematical ability. One definition of mathematical ability has been proposed by Hamley (1935), a mathematician and a psychologist. According to this definition, mathematical ability is a compound of general intelligence, visual imagery, and ability to perceive number and space configurations and to retain such configurations as mental patterns. The extent to which spatial ability enters into mathematical ability is suggested by several validity studies. Hills (1957) investigated the relationship between various aptitude tests and criterion performance in college mathematics. The test battery included two spatial tests—one of visualization and one of orientation—from the Guilford-Zimmerman Aptitude Survey (Guilford & Zimmerman, 1953). Subjects were 148 students in three institutions. The two spatial tests had relatively high correlations with course performance (for visualization, $r = .23$; for orientation, $r = .22$) compared to the verbal and reasoning tests administered ($r = .06$ each), which suggests a higher relative importance of spatial ability than verbal ability in college mathematics. And the space subtest of the Differential Aptitude Test battery (Bennett et al., 1974) is predictive of success in school geometry ($r = .57$) and quantitative thinking ($r = .69$). More recently, Eisenberg and McGinty (1977) have shown that spatial visualization test scores are higher among students in calculus courses than in other college courses.

Corroborative evidence has been provided by Smith (1948) and Werdelin (1961). Male superiority in understanding geometric principles and concepts has been reported (Saad & Storer, 1960), and Smith (1964) has suggested that the sex difference "may be another manifestation of the sex difference in spatial ability, reflecting a greater capacity on the part of boys to perceive, recognize and assimilate patterns within the conceptual structure of mathematics" (p. 123).

Orientation Ability

Recall that spatial orientation involves the comprehension of the arrangement of elements within a visual stimulus pattern, the aptitude to remain unconfused by the changing orientations in which a spatial configuration may be presented, and the ability to determine spatial orientation with respect to one's body. This definition raises the question of whether individual differences in various aspects of perceptual-cognitive functioning are a secondary consequence of differences with respect to spatial orientation ability. Empirical research in four areas is particularly relevant to this question: field dependence – field independence, sense-of-direction, Piagetian, and maze tasks.

Field dependence – field independence. One of the more familiar tasks on which sex differences have consistently been found is that of field dependence – field independence (Witkin, 1950; Witkin, Dyk, Faterson, Goodenough, & Karp, 1962; Witkin et al., 1954).

Two tests—the rod-and-frame test and the Embedded Figures Test—seem to have a strong spatial component. The rod-and-frame test, for instance, requires the examinee to adjust a rod to the vertical position in the absence of cues other than the luminescent square frame that surrounds the rod. The frame position as well as the position of the examinee may be tilted in various orientations. Adult females tend to be more dependent on the field in determining the vertical position of the rod than males (Bogo, Winget, & Gleser, 1970; Corah, 1965; Gross, 1959; Kato, 1965, Morf, Kavanaugh, & McConville, 1971; Okonji, 1969; Saarni, 1973; Schwartz & Karp, 1967; J. Silverman, Bucksbaum, & Stierlin, 1973; Vaught, 1965; Witkin et al., 1962; Witkin, Goodenough, & Karp, 1967), and the sex difference is apparent in adolescents as well (Graves & Koziol, 1971; Keogh & Ryan, 1971; J. Silverman et al., 1973; Canavan, Note 6).

The Embedded Figures Test requires the examinee to view and store in memory a simple geometric form and then to recall the

form by identifying it in a more complex geometric figure. The obvious spatial element in this task may account for the sex difference that is so widely documented for adolescents as well as for adults (e.g., Bieri, Bradburn, & Galinsky, 1958; Bigelow, 1971; Corah, 1965; Goldstein & Chance, 1965; Goodenough & Eagle, 1963; Graves & Koziol, 1971; Keogh & Ryan, 1971; Nash, 1973; Okonji, 1969; Witkin, 1950; Witkin et al., 1954). Sex differences on these tasks are less reliable among children under the age of 11 or 12 years (Maccoby & Jacklin, 1974; Witkin et al., 1954).

Sherman (1967) has provided the major theoretical articulation of the relationship between sex differences in spatial abilities and sex differences in field dependence, arguing that the sex difference in field dependence is an artifact of the sex difference in space perception. A sizable body of literature supports her hypothesis. Correlational studies have consistently demonstrated a strong relationship between tests of spatial orientation and measures of field dependence. Gardner et al. (1960) found correlations of Embedded Figures and rod-and-frame test scores with the Guilford-Zimmerman Spatial Orientation Test of .53 and .35, respectively. Thurstone (1944) reported correlations of .43 and .41 between two forms of the Gottschaldt Figures Test, similar to Witkin's Embedded Figures Test, and the Space Test of the Primary Mental Abilities test battery. This finding has been replicated by Podell and Phillips (1959).

Factor analytic studies indicate that tests of spatial abilities and field dependence–field independence emerge together in a factor similar in description to the Spatial Orientation factor discussed previously (Gardner et al., 1960; Hyde, Geiringer, & Yen, 1975; Podell & Phillips, 1959; Thurstone, 1944) and that sex differences in field dependence are eliminated after removing differences in spatial abilities (Hyde et al., 1975).

The presence of a spatial component in tests of field dependence–field independence seems to be a prerequisite for the appearance of sex differences. Measures of field dependence other than the rod-and-frame and Embedded Figure tests that do not have a spatial component (e.g., the rotator-match brightness constancy task and the body steadiness task) have not shown sex differences (Witkin et al., 1954). In light of the spatial nature of both the rod-and-frame and Embedded Figures tasks, the sex difference is understandable and should be narrowly interpreted, not generalized into an all encompassing statement about cognitive style (Harris, 1978).

Sense of direction. Spatial orientation ability is probably important in tasks requiring sense of direction. Berry's (1966) cross-cultural study comparing Eastern Canadian Eskimos from Baffin Island with members of the Temne tribe in Africa supports this hypothesis. The directional sense among Eskimo males and females fostered by extensive travel in hunting is reflected in higher performance on several tasks requiring spatial ability, including the Morrisby Shapes Test and a test of field dependence–field independence.

Spatial ability may enter into another task of directional sense—map reading. Money, Alexander, and Walker (1965) administered their Road Map Test of Direction Sense to over 1,000 children ranging in age from 7 to 18 years. The task consists of a schematic outline map of several city blocks with a standard route through the streets. The examinee is required to mentally follow the route, indicating verbally the direction of various turns (left or right with reference to point of origin). Males on the average performed significantly better than females and the differences were greatest between boys and girls of older ages.

Piagetian tasks. Tuddenham (1970) has developed several quantitative Piagetian tasks that require some spatial facility and that show sex differences favoring males. The tasks are Perspectives, Water Level, Tracks, Geometric Forms, and House Plans. On the Perspective task, examinees are required to select from among several photographs the one that shows how a small farm would look from various vantage points. The Water Level task involves problems that deal with the principle that water remains gravitationally horizontal regardless of the

tilt of the water's container. The Geometric Forms task involves the identification of flat patterns that can be folded to produce simple three-dimensional forms. Tracks, which involves the least amount of spatial skill, requires the examinee to correctly place a small car painted red on one side and blue on the other at various places on a spiral track. The House Plans task requires the construction of block buildings. Males' mean scores on all tasks except Tracks were higher than females' mean scores (Tuddenham, 1970).

The Water Level task, developed initially by Piaget and Inhelder (1956), was used by Thomas, Jamison, and Hummel, (1973) who found that 31% of adult females but 84% of males had mastered the principle that water remains gravitationally horizontal regardless of the tilt of the water's container. Early studies by Piaget and Inhelder (1956) determined that mastery of this principle occurred by about 12 years of age and that girls lag behind boys at various age levels (Thomas et al., 1973; Liben, Note 7; Thomas, Note 8). And Harris (1978) has suggested that the female lag in this principle's attainment is probably due to the spatial element of the task. Harris' hypothesis has been tested and supported by Geiringer and Hyde (1976). They found correlations between average errors on the Water Level task and performance on a test of spatial orientation of −.83 for 12th-grade males and −.97 for 12th-grade females. Corresponding correlations for 5th-grade males and females were somewhat lower (−.65 for males and −.42 for females) and, although a significant sex difference was found in performance on both tests among 12th graders, none was found among 5th graders. Analysis of covariance revealed that sex differences among 12th graders on the Water Level task disappeared once differences in spatial orientation ability were removed.

Maze tasks. Maze tasks were used as early as 1918 by Porteus in his attempt to design an alternative to measures of general intelligence and verbal ability. Designed for use by human subjects, the Porteus Maze Test (Porteus, 1918) has become an important and widely used testing device within the discipline of psychology (Riddle & Roberts, 1977). A sex difference showing male superior performance on the Porteus Maze Test has been a persistent finding in hundreds of studies since 1918 (Porteus, 1965). As in studies using standard tests of spatial ability, the sex difference does not reliably emerge until after age 11 or 12 (Batalla, 1943; Langhorne, 1948; McNemar, 1942; Porteus, 1965) and has failed to emerge in children younger than 6 years of age (Mattson, 1933; McGinnis, 1929).

Reference is seldom made in discussions of human spatial abilities to the considerable body of evidence that has shown a consistent superiority in maze-learning tasks for male rats (e.g., Barnes et al., 1966; Barrett & Ray, 1970; Cowley & Griesel, 1963; Dawson, 1972; Hubbert, 1915; McNemar & Stone, 1932; Sadownikova-Koltzova, 1926; Tomlin & Stone, 1933; Tryon, 1931).

Summary

We have illustrated the complexity of the problem suggested earlier—that of determining the depth and breadth of the field within which a Spatial factor may be found. Spatial visualization seems to be required in various perceptual-cognitive tasks involving the mental transformation of visual images, and it has been shown to be important for success in college mathematics, especially geometry and algebra.

Spatial orientation enters into such tasks as field dependence – field independence, map reading, and sense of direction. Various Piagetian tasks and maze tasks requiring an aptitude for remaining unconfused by changing orientations of a spatial configuration must certainly involve a strong spatial orientation element. There is an obvious need for further research to clarify the issues presented and to further specify the scope within which the Spatial Visualization and Spatial Orientation factors can be found.

Sources of Variance in Spatial Test Scores

An overwhelming impression conveyed by surveying the spatial abilities literature of the 1960s and 1970s in contrast to the preceding 5 decades is the redirection of interest from factor analytic studies that have con-

clusively distinguished two spatial abilities, visualization and orientation, to both correlational and experimental studies aimed at determining sources of variance in spatial test scores.

One conclusion concerning the factors that account for individual differences in spatial test scores is certain—the empirical evidence is compatible with a relatively broad range of intellectual positions. This evidence is reviewed in four categories, environmental, genetic, hormonal, and neurological, with emphasis on age and sex differences.

Environmental Influences

The importance of experiential factors in the development of spatial skills has been suggested by Berry (1966) in a previously discussed study. Berry compared Eastern Canadian Eskimos from Baffin Island with members of the Temne tribe of Africa on a number of perceptual-cognitive abilities. Eskimos were less field dependent than the Temne and obtained higher mean scores on tests of spatial abilities. Although males in the Temne tribe performed significantly better than Temne females on these measures, there were no significant differences between male and female Eskimos. Unlike Temne females, Eskimo females tend to share equally with males in experiences of hunting. To survive, Eskimo hunters must travel extensively on both land and sea and are required to orient themselves in a relatively featureless array of visual stimuli. Wandering from the home in the activity of hunting presumably fosters a "directional sense" and facilitates spatial skill (Berry, 1966). Although the results seem to suggest the importance of experiential factors in the development of spatial skills, cross-cultural differences are not necessarily environmental, particularly for long isolated groups such as the Temne of Africa and Canadian Eskimos.

Differential training and spatial perception. If experiential factors were important in fostering high spatial abilities, we might expect that training received in this area would result in improved performance on tests of spatial visualization and orientation. There is some evidence that improvement in perceptual judgments occurs as a function of controlled practice and training (Gibson, 1953; Goldstein & Chance, 1965; Kato, 1965; Salkind, 1976; Santos & Murphy, 1960; Van Voorhis, 1941; Witkin, Note 9), although ordinary school curriculum offerings are not always effective in developing spatial perception to the asymptote of an individual's ability (Brinkmann, 1966; Brown, 1954; Mendicino, 1958; Ranucci, 1952).

Blade and Watson (1955) reported significant increases by students on a test of spatial visualization during an engineering course. Positive effects have also been demonstrated by Brinkmann (1966). A small number of eighth-grade boys ($n = 14$) and girls ($n = 13$) were instructed in selected concepts of geometry and mental pattern folding during mathematics classes over a 3-week period. Posttraining test scores on the Space Relations Subtest of the Differential Aptitude Test (Bennett et al., 1974) were significantly higher than pretraining test scores for the experimental groups but not for a control group. Dailey and Neyman (Note 10) attempted to train vocational high school students on items similar to those found on two- and three-dimensional tests of orientation and visualization. Posttraining test scores obtained at the end of the academic year were significantly higher than pretraining test scores. These gains were shown to be greater for the trained group of students than for a control group.

Conflicting evidence in the literature is provided by Faubian, Cleveland, and Hassell (1942) who reported no differences on the Surface Development Test between a group of Air Corps recruits who had received training in drafting and blueprint reading and a matched control group. Churchill, Curtis, Coombs, and Hassell (1942) found slight but insignificant gains on the same test after a 9-week training course in engineering drawing. Myers (Note 11) found that Naval cadets who had received training in mechanical drawing scored no higher on spatial tests than cadets who had received no such training. And Ranucci (1952) and Brown (1954) have independently shown that courses in high school geometry did not result in increased performance on spatial tests.

An increase in mean performance levels after training on spatial tasks, even if it were a consistent finding, does not explain the sex difference. If we assume that the female deficit in human spatial abilities results from differential learning and that males are closer to the asymptote of their ability than females, then females should respond more favorably than males to training. This hypothesis is not strongly supported by available evidence. Unfortunately, sex differences in response to training were not systematically examined in the studies reviewed previously. However, a few studies are available. Preliminary results from Drauden's University of Minnesota dissertation research show no such affect (Drauden, Note 12). Teegarden (1942) examined the effect of increased time limits on test scores and found that increasing the time allowed to complete a form-board test did not significantly effect female performance. McGee (1978a) found no evidence for a differential response to training and practice on the Mental Rotations Test by females in comparison with males. Smith (1948) also found that females did not differentially respond to training. Female spatial test performance was not raised to the level of male performance as the result of training received in technical school. Thomas et al. (1973) reported sex differences for mastery of the principle that the surface of still water remains horizontal regardless of the tilt of the water's container. Whereas 84% of the males ($n = 62$) were aware of the principle, only 31% of the females ($n = 91$) were similarly aware. Training was successful in teaching the concept of "horizontality" to only 12 of the 63 females who were initially unaware. And McGee (Note 13) found that first-grade boys benefited more than girls from training on the Piagetian Water Level task.

Empirical research does not strongly support the hypothesis of a differential response to training by females than males. However, as pointed out by Sherman (1967), because of the unknowns involved in assuming what is relevant activity in increasing spatial abilities, it is difficult to know whether the sexes do in fact receive differential practice. Many activities in our culture are sex typed.

> Very few girls are found in the high school classes of mechanical drawing, analytical geometry, and shop. Spare-time activities of tinkering with the car, sports, model building, driving a car, direction finding, and map reading are sex-typed and might also be sources of differential practice. (Sherman, 1967, p. 295)

It seems highly likely that these and similar activities are involved in fostering spatial skills. To uncover this effect experimentally will require research designs more sensitive than those that have so far been used.

Genetic Influences

Accumulated evidence shows that spatial abilities are equally as or more heritable than verbal ability (Blewett, 1954; Block, 1968; Bock, 1973; DeFries et al., 1974, 1976; McGee, 1978c; Osborne & Gregor, 1968; Park et al., 1978; Vandenberg, 1962, 1967, 1968, 1969, 1971; Vandenberg, Stafford, & Brown, 1968; Williams, 1975; Bramble, Bock, & Vandenberg, Note 14; Thurstone, Thurstone, & Strandskov, Note 15) and much less correlated with traditional measures of environmental quality such as level of education and SES (Bock & Vandenberg, 1968; Marjoribanks, 1972; McGee, 1977; Vandenberg, 1971). A number of studies have suggested that spatial abilities may be enhanced by an X-linked, recessive gene (Bock & Kolakowski, 1973; Goodenough et al., 1977; Guttman, 1974; Hartlage, 1970; Stafford, 1961; Yen, 1975) and this hypothesis has served as a tentative explanation for the mode of genetic transmission and the sex difference in spatial test performance.

Spatial abilities and X-linked inheritance. Traits effected by the transmission of a single gene on the X chromosome are said to be X-linked and are determined to be either dominant or recessive based on the relative frequency of effected males and females in the population. If the X-linked trait were recessive, more males than females would be affected, whereas if the X-linked trait were dominant, more affected females than males would be expected. This is true because in a population at equilibrium, one

third of the X-linked genes are carried by males and two thirds are carried by females, since females inherit two X chromosomes (one from each parent) and males inherit only one. A recessive, X-linked trait will be expressed in hemizygous recessive males and homozygous recessive females but not in hemizygous dominant males nor in heterozygous or homozygous dominant females. Females with a double recessive genotype would be expected to occur in the population with a frequency q^2—the square of the frequency of males carrying the single recessive allele.

Where the frequency of the recessive, spatial-enhancing allele q equals either 0 or 1.00, the absolute sex difference $(q - q^2)$ will be 0 (Jensen, 1975). As the value q departs from 0 or 1.00, the absolute sex difference will increase. A gene frequency of .5 of the spatial-enhancing allele maximizes the sex difference, which sets the ratio of enhanced females to males at 1:2. Thus O'Connor's (1943) observation that only one fourth of all females score above the male median on tests of spatial ability, a finding replicated by numerous investigators (e.g., Bock & Kolakowski, 1973; Bouchard & McGee, 1977; Loehlin, Sharan, & Jacoby, 1978; Yen, 1975), is in accordance with the X-linked, recessive model.

In addition to fulfilling the basic requirement of explaining the greater proportion of spatializing males than females, the genetic X-linkage model predicts a characteristic pattern of family correlations different from that expected for an autosomal, polygenic trait. The model predicts a higher father–daughter than father–son correlation and a higher mother–son than mother–daughter correlation. Opposite sex pairs of siblings will tend to show less similarity than pairs of sisters, whereas the correlation between pairs of brothers should be an intermediate value. Sisters will be most similar because for brothers, the one X chromosome may be either of the mother's two, whereas for sisters the paternal X chromosome is identical (Hogben, 1932; Mather & Jinks, 1963; McKusick, 1964). Thus, under random mating and a recessive gene frequency of .5 (the frequency that best explains the mean sex difference and the shape of the male and female distribution), the expected order of family correlations is as follows: r sister–sister $>$ r mother–son $=$ r father–daughter $>$ r brother–brother $>$ r mother–daughter $>$ r brother–sister $>$ r father–son. The theoretically expected correlation, based on X-linkage, of .00 between fathers and sons is not easily predicted from environmental hypotheses in which modeling effects and shared experiences would ordinarily be expected to lead to higher same-sex than opposite-sex parent–child correlations. Consequently, the original studies supporting the X-linkage hypothesis (Bock & Kolakowski, 1973; Hartlage, 1970; Stafford, 1961) generated considerable interest, despite the fact that they were based on rather small samples and failed to provide correlations among siblings.

Several recent tests of the hypothesis have been conducted. This research is summarized in Table 2, which shows age-corrected family correlations for tests of spatial visualization and spatial orientation abilities, along with results on two miscellaneous tests that involve a spatial component but that are not ordinarily recognized as measures of visualization or orientation. Several of the studies used numerous tests, and some of the tests were used in more than one study. Thus, in addition to comparing similarities (and dissimilarities) among tests, it is possible to examine the extent to which the same tests yield similar correlation patterns across samples.

Only two studies in the literature (Bouchard & McGee, 1977; Loehlin et al., 1978) report the complete array of family correlations consisting of both parent–child and sibling correlations. In each of these studies, the father–son correlation equals or exceeds the mother–son correlation; therefore these results do not conform to the expected pattern. In Bouchard and McGee's (1977) study the difference between the brother–brother and the sister–sister correlations is highly significant ($p < .005$) in the direction opposite that predicted by the X-linkage model. The expected pattern of parent–child correlations (with opposite-sex parent–child correlations highest, the mother–daughter correlation intermediate, and the father–son correlation lowest), although obtained in the

original studies supporting the X-linkage hypothesis (Bock & Kolakowski, 1973; Hartlage, 1970; Stafford, 1961), has not been obtained for any spatial tests used in four recent, larger family studies (Bouchard & McGee, 1977; DeFries et al., 1976; Loehlin et al., 1978; Park et al., 1978). These results provide weak evidence, if any, for the spatial-enhancing effect of the X-linked recessive gene postulated by Stafford (1961). The idea, however, that different assessments of spatial abilities (e.g., two-dimensional vs. three-dimensional tasks, rotation vs. transformation of spatial objects, analytic vs. gestalt processing, visualization vs. orientation) have different genetic structures should appeal to those investigators who are reluctant to abandon the search for the spatial gene. An important contribution to this literature would be a family study providing the full array of intrafamilial correlations for spatial visualization and spatial orientation tests, including the three tests that have shown the pattern of correlations predicted by the X-linked model: the Identical Blocks Test (Stafford, 1961), the Differential Aptitude Space Test (Hartlage, 1970), and the adapted Guilford-Zimmerman Spatial Visualization Test (Bock & Kolakowski, 1973). It is not at all clear, from the few attempts to address these issues (Guttman, 1974; Loehlin et al., 1978; Yen, 1975) just what kinds of spatial test performance the X-linked gene should be expected to influence most. "Clearly, the final word is not yet in" (Loehlin et al., 1978, p. 40).

Hormonal Influences

To what extent are hormonal differences in males and females responsible for the observed sex difference in spatial test performance? A small body of studies has addressed this question. Petersen (1976), for example, demonstrated a curvilinear relationship between physical androgenicity and certain aspects of cognitive functioning, namely, verbal fluency and spatial ability. Measures in both boys and girls at ages 13, 16, and 18 were made of sex hormone influence inferred from degree of secondary sex characteristic development, which is known to be under gonadal hormone influence (Tanner, 1969).

Scores were available from two measures of spatial ability (including the Primary Mental Abilities Space Test, Thurstone & Thurstone, 1965) and from two measures of verbal fluency. Her results showed that less androgenized (less masculine) males (assessed on the basis of various physical characteristics including hip size, shoulder width, and muscle strength) scored higher on the spatial tests than boys with a more androgenized (more masculine) body type. The positive correlations were highest for the 18 year olds, lowest for the 13 years olds, and intermediate for the 16 year olds. These findings support those presented by Broverman, Klaiber, Kobayashi, and Vogel (1968), who found that more androgenized males scored higher on verbal fluency than on spatial ability tests. For females, however, Broverman et al. found different results: Females with high androgen levels (again rather crudely determined on the basis of physical characteristics such as narrow hips, wide shoulders, solid muscles, and small breasts) had higher spatial scores than females with low androgen levels.

Other evidence has accumulated that highly masculinized males have a tendency toward lower spatial scores. For example, Klaiber, Broverman, and Kobayashi (1967) tested male college students using two simple repetition tasks and two spatial tasks. Scores on these spatial tasks were correlated with measures of masculinity (large chest and biceps and pubic hair distribution). Results showed a positive correlation with performance on the simple tasks of repetition but a negative correlation with performance on the spatial tasks. In another study, Ferguson and Maccoby (cited in Maccoby, 1966) found that boys with high spatial scores were rated by their peers as less masculine than boys with low scores.

How are these data to be interpreted? High body androgenization is associated with *low* spatial scores among males (Ferguson & Maccoby, cited in Maccoby, 1966; Klaiber et al., 1967; Petersen, 1976) and with ***high*** spatial scores among females (Broverman et al., 1968; Petersen, 1976). It might be

that spatial abilities are facilitated not by any absolute level of androgen but rather by an optimal estrogen–androgen balance. Unfortunately there exists a paucity of evidence to support this contention. One test comes from a study of Kwashiorkor feminized males (Dawson, 1967a, 1967b). West African children suffering from Kwashiorkor (a disease resulting from prolonged subsistence on diets deficient in protein) and the accompanying protein-deficiency-induced endocrinological dysfunction of the liver, which prevents the normal inactivation of the production of estrogen in the male (Stuart-Mason, 1963), exhibited lower spatial and numerical ability and greater field dependence, as compared to normal controls, in addition to demonstrating greater verbal ability. And the curvilinear nature of the relationship between body androgenicity and spatial ability found by Petersen (1976) indicates that at least a minimum androgen level is required for normal spatial ability. It follows from these findings that the superior spatializer of either sex is less sexually differentiated than are nonspatializers. That is, the estrogen–androgen balance would be optimal and consequently spatial abilities would be highest for males low in androgen and for females high in androgen. We might even suggest that for females, the more androgen one has the better, thus explaining why individuals with Turner's syndrome (phenotypic females, the majority of whom has the single X chromosomes XO rather than the normal female XX pairs and no gonadal hormones) demonstrate poorer spatial abilities (Alexander, Ehrhardt, & Money, 1966; Alexander & Money, 1966; Alexander, Walker, & Money, 1964; Garron, 1970, 1977; Money, 1963; Money & Granoff, 1965; Serra, Pizzamiglio, Boari, & Spera, 1978; Silbert, Wolff, & Lilienthal, 1977), poorer direction sense (Alexander et al., 1964), and greater field dependence (Serra et al., 1978) than both males who also have single X chromosomes and genetically normal females.

The questions raised in this section point to the obvious need for research aimed at clarifying the relationship between somatic androgenization and the evidence reviewed earlier for an X-linked recessive gene influence on spatial skill enhancement. The finding of better spatial skill in late-maturing, less androgenized boys than in early-maturing, more androgenized boys (Broverman et al., 1968) suggests the operation of an X-linked gene controlling the timing of release of androgen rather than the expression of spatial skill directly (Bock & Kolakowski, 1973).

The suggestion made is that there exists a sex-linked influence on within-sex variation in somatic androgenicity. However, this is a question that awaits empirical investigation. Future research might be aimed at determining the extent of this influence on between-sexes variation in spatial abilities. The methods of measuring body androgenization used by Petersen (1976) and by Broverman et al. (1968), based on the analysis of physical characteristics including muscle development, body shade, genital or breast size, and pubic hair distribution obtained by rating photographs, are crude and imprecise indices of sexual differentiation controlled by estrogen–androgen balance. Until more direct methods of hormonal assay are employed on larger samples, the precise nature of the relationship between spatial abilities and hormonal balance will remain an open question.

Neurological Influences

Neurological studies showing variations in the lateral organization of the human brain provide experimental evidence for a structural source of the variation in human spatial abilities. Recent work on hemispheric specialization suggests (a) that the right cerebral hemisphere is specialized for spatial processing and (b) that males have greater hemisphere specialization than females. These conclusions are supported from several different types of evidence to be reviewed.

Hemispheric specialization. Language function was the first higher mental process found to be asymmetrically represented in the human brain, and it remains the best documented case of hemispheric specialization (Nebes, 1974). Recent studies have established anatomical bases for the special-

ization of both verbal and nonverbal information processing in human subjects. Kimura (1961) was probably the first investigator to employ Broadbent's (1954) technique of dichotic listening for the examination of hemispheric specialization when she demonstrated that when pairs of contrasting digits were presented simultaneously to the right and left ears, those presented to the right ear were more accurately reported. Right ear advantage for the processing of easy-to-verbalize stimuli (e.g., numbers, words, and letters) has since been confirmed (Milner, Taylor, & Sperry, 1968; Sparks & Geschwind, 1968; Studdert-Kennedy & Shankweiler, 1970).

Conversely, a left ear (right hemisphere) advantage for the processing of difficult-to-verbalize stimuli (e.g., melodies, sonar signals, and abstract patterns of sound) has also been demonstrated (Curry, 1967; Kimura, 1964, 1966; Shankweiler, 1966; Spreen, Benton, & Fincham, 1965; Vignolo, 1969; Chaney & Webster, Note 16).

Other data demonstrate convincingly that each cerebral hemisphere primarily subserves its contralateral limb and binocular visual hemifield (Buffery & Gray, 1972) and that in about 96% of the normal adult population, cerebral dominance for verbal functions (i.e., tasks requiring semantic memory, manipulation, and production) is subserved by the left hemisphere, whereas the right hemisphere predominates in subserving nonverbal functions (i.e., tasks requiring perception and manipulation of visual images) (Bogen & Gazzaniga, 1965; Buffery, 1968; Buffery & Gray, 1972; Levy, 1976a; Searleman, 1977; Witelson, 1976).

Several investigations of patients with unilateral brain lesions have demonstrated spatial abilities to be more affected by right than by left cerebral injury (Kimura, 1967; McFie, Piercy, & Zangwill, 1950; Milner, 1962). Costa and Vaughan (Note 17) found that right-lesion patients ($n = 18$) scored significantly lower ($p < .05$) than left-lesion patients ($n = 18$) on the Block Design subtest of the Wechsler Adult Intelligence Scale, with both normal and extended time limits. Similarly, it has been demonstrated that patients who have suffered the loss of their left temporal lobe show impaired memory for verbal materials but nonsignificant performance decrements on tasks such as memory for faces (Milner et al., 1968) and maze learning (Corkin, 1965; Milner, 1965). In a more recent study, Kershner and King (1974) examined laterality of cognitive functions among hemiplegic children and found similar results. Twenty-one children were administered the Wechsler Intelligence Scale for Children (WISC) and the Reitan-Indiana Neurological Test. The left hemiplegics (right-brain-damaged) children ($n = 7$) were poorer than normals on visuoperceptual performance tasks ($p < .05$) but showed no significant impairment, relative to normals, on any of the WISC verbal tests. Right hemiplegics (left-brain-damaged) children ($n = 7$) were poorer than normals in verbal intelligence ($p < .05$).

Although sample sizes are small among clinical populations, clinical studies of the effects of unilateral brain damage, reviewed previously, and commissurotomy (Sperry, 1968, 1973; Sperry, Gazzaniga, & Bogen, 1969) on verbal and spatial tasks corroborate tachistoscopic perceptual data and provide direct evidence for the conclusion that the right cerebral hemisphere is specialized for spatial processing.

Hemispheric specialization and sex differences in spatial abilities. To what extent do sex differences in hemispheric specialization underly male superiority on tasks requiring spatial abilities? A review of clinical and experimental data indicates that the right cerebral hemisphere is specialized for spatial processing and that the cerebral hemispheres of males and females tend to show differences in specialization for verbal and spatial functions. The conclusions that males have greater right hemisphere specialization than females is supported by data from tachistoscopic perceptual studies (Ehrlichman, 1972; Kimura, 1969, 1973; McGlone & Davidson, 1973), clinical studies (Lansdell, 1962, 1968a, 1968b, 1973; McGlone & Kertesz, 1973), and studies of anatomical differences between the sexes (Geschwind, 1974; Lansdell & Davie, 1972; Wada, 1974; Witelson & Pallie, 1973). Much of this literature has been reviewed elsewhere (cf. Buffery & Gray,

1972; Harris, 1978; Harshman & Remington, 1976).

The major opposition to the conclusion that males have greater right hemisphere specialization and thus greater spatial ability than females has been proposed by Buffery and Gray (1972). Their theory that females are more lateralized than males for both language and spatial skills is supported mainly from developmental data on children. However, as Buffery and Gray themselves point out, "sex differences in children are difficult to interpret when there is an advantage in favor of girls, since this may always be due to their general maturational advantage over boys" (p. 131). Moreover, recent developmental studies of hemispheric specialization are consistent with the conclusion that boys have greater right hemisphere specialization than girls and that girls are more bilateral in their cerebral representation of verbal and spatial functions.

Knox and Kimura (1970), for example, studied dichotic listening to nonverbal stimuli (environmental and animal noises such as dish washing, phone dialing, clock ticking, dog barking). Subjects were 80 right-handed children between 5 and 8 years of age. Males showed a greater left ear (right hemisphere) superiority than females across all ages.

Witelson (1976) presented children ranging in age from 3 to 13 years with a tactual version of the dichotic recognition technique. All children were originally assessed as being right-handed. Examinees were instructed to touch unfamiliar four- to eight-sided shapes and then to identify the forms by pointing to a visual display of a group of shapes. Boys ($n = 165$) at age 5 and beyond showed a significant left-hand (right hemisphere) advantage; there was no hand difference for the 3- to 4-year-olds. Girls ($n = 165$) showed significant left-hand superiority but not until after age 13. Witelson concluded that the right hemisphere may be specialized for spatial processing (the detection of shapes) earlier in boys than in girls. Other evidence of earlier right hemisphere specialization in boys than girls for processing of nonauditory, tactual configurations has been provided from the investigation of Braille reading in both normal (Rudel, Denckla, & Spalten, 1973) and blind subjects (Hermelin & O'Connor, 1971a, 1971b). Since Braille characters are symbols of alphabet letters, a left hemisphere (right-hand advantage for reading Braille might be expected. It has been observed, however (Hermelin & O'Connor, 1971b), that right-handed blind individuals have a clear advantage for reading Braille with the fingers of their left hand. Hermelin and O'Connor (1971a) have suggested that for the blind, Braille symbols are processed as spatial configurations, not as linguistic symbols, and are as a result processed by the right cerebral hemisphere. A direct test of this hypothesis has been provided by Rudel et al. who examined normal children. Right-handed males and females ($n = 80$) between 7 and 14 years of age learned 12 Braille letters, 6 with each hand. Results indicated that 7- and 8-year-old boys performed equally well with both hands in the Braille, paired-associate learning task but that the girls of the same age showed right-hand superiority. Left-hand (right hemisphere) superiority emerged for both boys and girls at later ages (13 and 14 years), but the difference between right- and left-hand scores was statistically significant only for the boys, indicating an earlier and perhaps superior pattern of right hemisphere development in boys than girls.

Another opposing hypothesis to that of greater right hemisphere specialization in males than females has been proposed by Harris (1978). According to Harris, "the male eventually equals and then surpasses the female in degree of left hemisphere lateralization, so that in adulthood, language in females is bilaterally represented," thus impeding her spatial ability (p. 460). Support for Harris' first postulate—that of greater bilateralization of language function in females than males—is provided from studies of normal (Bryden, 1966; Remington, Krashen, & Harshman, Note 18) as well as clinical populations (Lansdell, 1961, 1962; McGlone & Kertesz, 1973). Harris dismisses developmental studies of hemispheric specialization, however, which consistently show earlier and greater left hemisphere specialization of language function in

girls than boys (Buffery, 1970, 1971a, 1971b, 1971c; Kimura, 1963; Pizzamiglio & Cecchini, 1971; Bryden, Allard, & Scarpino, Note 19).

Harris (1978) provides support for his second postulate—that bilateral cerebral representation impedes spatial skills—mainly on the basis of studies of left-handers. The assumption is that left-handers tend to be less well lateralized (more bilateral) than right-handers in cerebral representation of verbal and spatial functions (Bryden, 1966; Goodglass & Quadfasel, 1954; Remington et al., Note 18). The implication is that left-handers, like females, should score lower on tests of spatial ability than right-handers, since they are less well lateralized. Studies supporting the relationship between left-handedness and deficits on spatial tasks (James, Mefferd, & Wieland, 1967; Levy, 1969, 1976b; McGlone & Davidson, 1973; Miller, 1971; Nebes, 1971; Nebes & Briggs, 1974; A. Silverman, Adevai, & McGough, 1966) are based on small samples, and differences associated with sex are not always examined.

Numerous other studies (Annett & Turner, 1974; Fagan-Dubin, 1974; Kutas, McCarthy, & Donchin, 1975; McGee, 1976, 1978b; Newcombe & Ratcliff, 1973; Sherman, in press) report conflicting evidence regarding the prediction of poorer overall performance on spatial tasks by left- than right-handers. As noted by Hardyck and Petrinovich (1977), the data indicating that left-handedness is associated with deficits of various kinds is far from compelling.

A related problem associated with Harris' (1978) hypothesis is the assumption that left-handers are more bilateral than right-handers in their cerebral representation of verbal and spatial functions. Bilaterality of cerebral function seems to be present in the left-handed only when there is a family history of left-handedness (Hardyck & Petrinovich, 1977) and is *not* a characteristic of the nonfamilial left-handed individuals who as a group tend to be organized for cerebral specialization exactly as are the right-handed.

In summary, the clinical and experimental neurological literature suggests conclusively that the right cerebral hemisphere is specialized for spatial processing and that males have greater right hemisphere specialization than females. Further research is needed to determine the causal relationship, if any, between sex differences in hemisphere specialization and sex differences in spatial abilities.

Conclusion

Six conclusions are warranted. First, a plethora of factor analytic studies since the 1930s have provided strong and consistent support for the existence of at least two distinct spatial abilities—visualization and orientation. Spatial visualization is the ability to mentally rotate, manipulate, and twist two- and three-dimensional stimulus objects. Spatial orientation ability includes the comprehension of the arrangement of elements within a visual stimulus pattern, the aptitude to remain unconfused by the changing orientations in which a spatial configuration may be presented, and an ability to determine spatial orientation with respect to one's body. Second, visualization and orientation abilities are more highly correlated with success in a number of technical, vocational, and occupational domains than is verbal ability, making them important variables in applied psychology. Third, sex differences in various aspects of perceptual-cognitive functioning (e.g., mathematics and field independence) are a secondary consequence of differences with respect to spatial visualization and spatial orientation abilities. Fourth, sex differences on tests of spatial visualization and orientation as well as on numerous tasks requiring these abilities do not reliably appear until puberty. Fifth, spatial abilities are known to be influenced almost as much by genetic factors as is verbal ability in all populations studied; however, the X-linked recessive gene hypothesis that has served as a tentative explanation for sex differences in spatial abilities and for the mode of genetic transmission is not supported strongly in recent studies. Sixth, the development of sex differences in spatial skills is likely related to sex differences in the development of hemisphere specialization. Recent work in hemisphere specialization demonstrates conclusively that the right cerebral

hemisphere is specialized for spatial processing and that males have greater right hemisphere specialization than females.

Alternatives to Simonton's Analyses of the Interrupted and Multiple-Group Time-Series Designs

James Algina

University of Florida

Hariharan Swaminathan
School of Education
University of Massachusetts, Amherst

Statistical procedures for analyzing the interrupted time-series and the multiple-group time-series designs are outlined. The procedures are applicable when several subjects are observed on several pretreatment and posttreatmeant occasions, and the number of subjects is greater than the number of occasions.

Simonton (1977) discussed the use of several linear models for the analysis of data arising in the interrupted time-series design and the multiple-group time-series design. The interrupted time-series design consists of measuring the same subjects on several pretreatment occasions, introducing a treatment, and measuring the subjects on several posttreatment occasions. In the multiple-group time-series design, two groups of subjects are used. In this case, the experimental group is treated in the same manner as the single group in the interrupted time-series design. The control group is measured on the same occasions as the experimental group but does not receive the treatment. Typically, assignment of subjects to the two groups is nonrandom, although the treatment may be assigned randomly to the groups.

The linear models discussed by Simonton (1977) are similar to the univariate polynomial trend analysis model that can be used to estimate regression curves with a quantitative independent variable. However, there is a major difference between the data for which univariate trend analysis is appropriate and the data obtained in the time-series designs. The difference is that to use the univariate trend analysis, different subjects are used at each level of the independent variable. Therefore, it may be reasonable to assume that the residuals from the polynomial trend function are uncorrelated, an assumption that is required for the use of ordinary least squares estimates. The reasonableness of this assumption derives from the fact that each residual characterizes a different subject. Since in the time-series designs the same subjects are measured at each occasion, the residuals in any model for time-series data characterize the same individuals and therefore are likely to be correlated. As a result, ordinary least squares estimates of the parameters may not be efficient and hence should not be used. Simonton recognized this problem and suggested the use of modified generalized least squares estimators. This is a reasonable suggestion.

The analyses discussed by Simonton (1977) consist of estimating the parameters of the linear model and then testing hypotheses about the parameters to examine the hypothesis of a treatment effect. In general, we do not have any objections to the models proposed by Simonton for the interrupted time-series design. Our concern is with the analyses advocated by Simonton, and one purpose of this article is to propose alternative statistical analyses. With regard to the multiple-group time-series design, our position is that the aims of Simonton's analyses can be realized using profile analysis. Therefore, a second purpose of this article is to describe a profile analysis of the data arising from a multiple-group time-series design.

In all of the following, we assume that the number of subjects (N) exceeds the number of occasions (p). Simonton (1977)

suggested that N should be larger than p, preferably twice as large. Hence, our criterion for N is not more restrictive than Simonton's.

Critique of Simonton's Analyses

It can be shown that each of Simonton's (1977) models for the interrupted time-series design can be expressed as a special case of

$$\bar{\mathbf{X}} = \mathbf{A}\beta + \mathbf{e} \tag{1}$$

where $\bar{\mathbf{X}}$ is the $(px1)$ sample mean vector, $\mathbf{A}$ is a (pxr) known-design matrix, β is an $(rx1)$ vector of unknown parameters, and $\mathbf{e}$ is a $(px1)$ random vector of residuals. The vector $\bar{\mathbf{X}}$ is calculated from the N realizations, $\mathbf{X}_i$, of the random vector $\mathbf{X}$. The variance–covariance matrix of $\mathbf{X}$ is Σ. If the model in Equation 1 is correct, then the population mean vector $\mu = \mathbf{A}\beta$ and the variance–covariance matrix of $\mathbf{e}$, and hence, $\bar{\mathbf{X}}$, is $\mathbf{V} = \Sigma/N$.

The vector β should not be estimated using the ordinary least squares estimator $\hat{\beta}_1 = (\mathbf{A}'\mathbf{A})^{-1}\mathbf{A}'\bar{\mathbf{X}}$, since it may not be efficient if the variance–covariance matrix of $\mathbf{e}$ is not $\sigma^2 I$, (i.e., if the elements of $\mathbf{e}$ are correlated or have unequal variances). An appropriate estimator for β is the modified generalized least squares estimator $\hat{\beta} = (\mathbf{A}'\hat{\mathbf{V}}^{-1}\mathbf{A})^{-1}\mathbf{A}'\hat{\mathbf{V}}^{-1}\bar{\mathbf{X}}$, where $\hat{\mathbf{V}}$ is an estimator of $\mathbf{V}$. The problem in using $\hat{\beta}$ is developing an estimator for $\mathbf{V}$.

As noted above, Simonton (1977) recognized that the elements of $\mathbf{e}$ are likely to be correlated and attempted to use $\hat{\beta}$ by calculating an estimate of $\mathbf{V}$ under the assumption that the elements of $\mathbf{e}$ conform to a first-order stationary autoregressive model. This implies that

$$e_t = \rho e_{t-1} + \delta_t, \quad t = 2, \ldots, p$$

with the mean of $e_t = 0$ and the variance of e_t constant for $t = 1, \ldots, p$. This assumption is unlikely to be correct for two reasons. First, Lord (1963) has shown that the variance of a variable is likely to increase over time. Second, Jöreskog (1970) has pointed out that an autoregressive model is unlikely to fit data perturbed by measurement error.

More important than the likely failure of the data to meet the autoregressive assumption is that it is not necessary to make the assumption to estimate β, provided that $N > p$. Use of $\hat{\beta}$ requires an estimator for $\mathbf{V} = \Sigma/N$. This can be accomplished by using the sample variance-covariance matrix

$$\mathbf{S} = \frac{1}{N-1}\sum_{i=1}^{N} (\mathbf{X}_i - \bar{\mathbf{X}})(\mathbf{X}_i - \bar{\mathbf{X}})'$$

as an estimator of Σ and using $\mathbf{S}/N$ as an estimator of $\mathbf{V}$. This approach requires no assumptions about the stochastic process generating $\mathbf{e}$. The estimator $\hat{\beta}$ then becomes $\hat{\beta} = (\mathbf{A}'\mathbf{S}^{-1}\mathbf{A})^{-1}\mathbf{A}'\mathbf{S}^{-1}\bar{\mathbf{X}}$.

A second problem with the analyses suggested by Simonton (1977) is that he did not provide a method for evaluating the fit of the model to the data. Therefore, it is possible to estimate the vector β and use this estimate to make an inference about a treatment effect even though the model fits the data badly. A third problem is that Simonton proposed the use of approximate tests of significance to test hypotheses about β. However, exact tests of significance are available when $\mathbf{S}$ is used to estimate Σ, and use of these tests is preferable to use of the approximate tests advocated by Simonton.

With regard to the multiple-group time-series design, our major criticism was discussed previously. The procedures reported by Simonton, and their attendant assumptions, are unnecessary since the aims of his procedures can be accomplished using profile analysis.

Interrupted Time-Series Design

As noted above the models discussed by Simonton (1977) are special cases of the linear model given in Equation 1. The models discussed by Simonton are called changed-level (with permanent, transient, or dampened change level) and changed-slope models. The first purpose of this section is to illustrate how each of these models is expressed in terms of Equation 1. Suppose that the subjects are measured on six occasions, three pretreatment and three posttreatment. The permanent changed-level model is expressed as

$$\begin{bmatrix} \bar{X}_1 \\ \bar{X}_2 \\ \bar{X}_3 \\ \bar{X}_4 \\ \bar{X}_5 \\ \bar{X}_6 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 1 & 0 \\ 1 & 0 \\ 1 & 1 \\ 1 & 1 \\ 1 & 1 \end{bmatrix} \begin{bmatrix} \beta_0 \\ \beta_1 \end{bmatrix} + \begin{bmatrix} e_1 \\ e_2 \\ e_3 \\ e_4 \\ e_5 \\ e_6 \end{bmatrix}.$$

The model states that the means for the pretreatment occasions are at the same level. After the treatment, the means move to a new level. The hypothesis that $\beta_1 = 0$ is tested to determine if a treatment effect has occurred. If the hypothesis that $\beta_1 = 0$ cannot be rejected, then the means for the entire time-series design are at the same level and a treatment effect cannot be inferred.

The transient changed-level model can be expressed as

$$\begin{bmatrix} \bar{X}_1 \\ \bar{X}_2 \\ \bar{X}_3 \\ \bar{X}_4 \\ \bar{X}_5 \\ \bar{X}_6 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 1 & 0 \\ 1 & 0 \\ 1 & 1 \\ 1 & 0 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} \beta_0 \\ \beta_1 \end{bmatrix} + \begin{bmatrix} e_1 \\ e_2 \\ e_3 \\ e_4 \\ e_5 \\ e_6 \end{bmatrix}.$$

Here the model states that the mean for the occasion immediately following the treatment moves to a level different from the common level of all the other means. For the same reason as with the previous model, the hypothesis that $\beta_1 = 0$ is of interest.

The dampened changed-level model is expressed as

$$\begin{bmatrix} \bar{X}_1 \\ \bar{X}_2 \\ \bar{X}_3 \\ \bar{X}_4 \\ \bar{X}_5 \\ \bar{X}_6 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 1 & 0 \\ 1 & 0 \\ 1 & 1 \\ 1 & .5 \\ 1 & .25 \end{bmatrix} \begin{bmatrix} \beta_0 \\ \beta_1 \end{bmatrix} + \begin{bmatrix} e_1 \\ e_2 \\ e_3 \\ e_4 \\ e_5 \\ e_6 \end{bmatrix}.$$

The model states that the means for the pretreatment occasions are all at the same level. After the treatment the mean increases, but over time the means tend to drop back to the initial level. Again, the hypothesis that $\beta_1 = 0$ is tested.

As Simonton (1977) noted, the previous models all assume that the population means would be equal if it were not for the intervening treatment. An alternative assumption is that there is a linear or higher order trend in the population means. Such an assumption can easily be incorporated in any of the changed-level models above. To illustrate, suppose that there is a hypothesized quadratic trend and a dampened level change. The model can be expressed as

$$\begin{bmatrix} \bar{X}_1 \\ \bar{X}_2 \\ \bar{X}_3 \\ \bar{X}_4 \\ \bar{X}_5 \\ \bar{X}_6 \end{bmatrix} = \begin{bmatrix} 1 & -5 & 5 & 0 \\ 1 & -3 & -1 & 0 \\ 1 & -1 & -4 & 0 \\ 1 & 1 & -4 & 1 \\ 1 & 3 & -1 & .5 \\ 1 & 5 & 5 & .25 \end{bmatrix} \begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \beta_3 \end{bmatrix} + \begin{bmatrix} e_1 \\ e_2 \\ e_3 \\ e_4 \\ e_5 \\ e_6 \end{bmatrix}.$$

In this model, the parameter of interest is β_3. If the hypothesis that $\beta_3 = 0$ cannot be rejected, then a quadratic curve adequately fits the data, and hence, a treatment effect cannot be inferred. The logic here is that the same trend is evident both in the pretreatment and posttreatment means, so it is difficult to claim that the treatment had an effect. This notion was discussed by Campbell (1963).

The changed-slope model discussed by Simonton (1977) can be expressed as

$$\begin{bmatrix} \bar{X}_1 \\ \bar{X}_2 \\ \bar{X}_3 \\ \bar{X}_4 \\ \bar{X}_5 \\ \bar{X}_6 \end{bmatrix} = \begin{bmatrix} 1 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 1 \end{bmatrix} \begin{bmatrix} \beta_1 \\ \beta_2 \\ \beta_3 \\ \beta_4 \end{bmatrix} + \begin{bmatrix} e_1 \\ e_2 \\ e_3 \\ e_4 \\ e_5 \\ e_6 \end{bmatrix}.$$

The model states that there is a linear trend in the pretreatment and posttreatment data. With this model there are two null hypotheses to be tested: the hypothesis of a common intercept, H_{01}: $\beta_1 = \beta_3$, and the hypothesis of a common slope, H_{02}: $\beta_2 = \beta_4$. If neither hypothesis is rejected, then the linear trend for both the pretreatment and posttreatment data is the same, and hence, a treatment effect cannot be inferred. If either is rejected, the hypothesis of a treatment effect is supported. With more pretreatment and posttreatment occasions, this model can be generalized to include higher order trends. The analysis of data that used a linear model was discussed by Algina and Swaminathan (1977). The analysis of data that used a curvilinear model was discussed in detail by Swaminathan and Algina (1977). At this point the discussion turns to the statistical procedures for testing the fit of a particular model to the data and for testing hypotheses about the parameters of the model. These procedures are based on an article by Rao (1959) and have been discussed by Swaminathan and Algina.

Let $\epsilon(\ )$ denote the expectation operator. Since $\epsilon(\bar{\mathbf{X}}) = \mu$, it follows that

$$\epsilon(\bar{\mathbf{X}}) = \mu = \mathbf{A}\beta + \epsilon(\mathbf{e}). \tag{2}$$

Let $\mathbf{Q}[(p - r)xp]$ be a nonzero matrix constructed so that $\mathbf{QA} = \mathbf{0}$. The matrix $\mathbf{Q}$ can be chosen as a basis for the matrix $[\mathbf{I} - \mathbf{A}(\mathbf{A}'\mathbf{A})^{-1}\mathbf{A}']$. Premultiplying Equation 2 by $\mathbf{Q}$, we obtain

$$\mathbf{Q}\mu = \mathbf{QA}\beta + \mathbf{Q}\epsilon(\mathbf{e}),$$
$$= \mathbf{Q}\epsilon(\mathbf{e}).$$

As noted above, if the hypothesized model is correct, then $\mu = \mathbf{A}\beta$, and hence $\epsilon(\mathbf{e}) = \mathbf{0}$. Therefore, if the model is correct, $\mathbf{Q}\mu = \mathbf{0}$. On the other hand, if the hypothesized model given by Equation 1 is not correct, then $\mathbf{Q}\mu \neq \mathbf{0}$. Therefore, to test the adequacy of the model, the hypothesis

$$H_0\colon \mathbf{Q}\mu = \mathbf{0} \tag{3}$$

is tested. Failure to reject the hypothesis given by Equation 3 supports the contention that Equation 1 is the correct model. Conversely, rejection of the hypothesis indicates that Equation 1 does not adequately fit the data.

It is well-known that the hypothesis given by Equation 3 may be tested using Hotelling's T^2 statistic,

$$T^2 = N\bar{\mathbf{X}}'\mathbf{Q}'(\mathbf{QSQ}')^{-1}\mathbf{Q}\bar{\mathbf{X}}, \tag{4}$$

where $\bar{\mathbf{X}}$ is the sample mean vector, and $\mathbf{S}$ is the sample variance–covariance matrix. The test statistic may be transformed to the variate

$$F = \frac{N - p + r}{(p - r)(N - 1)} T^2,$$

which is compared to the $(1 - \alpha)$th fractile of the F distributions with $p - r$ and $N - p + r$ degrees of freedom. The matrix $\mathbf{Q}$ is not unique, but Rao (1959) showed that the test statistic is invariant to the choice of $\mathbf{Q}$.

If the test for the fit of the model to the data indicates that the model is inadequate, then a new model must be proposed. If the model adequately fits the data, then the vector β is estimated and the relevant hypothesis is tested. The modified generalized least squares estimate of β is $\hat{\beta} = (\mathbf{A}'\mathbf{S}^{-1}\mathbf{A})^{-1}\mathbf{A}'\mathbf{S}^{-1}\bar{\mathbf{X}}$.

All of the hypotheses concerning β can be expressed as special cases of the hypothesis $\mathbf{G}\beta = \mathbf{0}$, where $\mathbf{G}$ is a (kxr) matrix of rank $k \leq r$. Rao (1959) has shown that this hypothesis can be tested using the test statistic

$$F = \frac{N(N+r-p-k)\hat{\beta}'\mathbf{G}'[\mathbf{G}(\mathbf{A}'\mathbf{S}^{-1}\mathbf{A})^{-1}\mathbf{G}']^{-1}\mathbf{G}\hat{\beta}}{k[(N-1)+T^2]}, \tag{5}$$

where T^2 is the quantity defined in Equation 5. The quantity F follows the F distribution with k and $N - k - p + r$ degrees of freedom. For the changed-level models, $\mathbf{G}$ is a $(1xr)$ vector, say $\mathbf{g}'$, with 0 as the first $r - 1$ elements and 1 as the remaining element. In this case, the test statistic reduces to

$$F = \frac{N(N + r - p - 1)(\mathbf{g}'\hat{\beta})^2}{\mathbf{g}'(\mathbf{A}'\mathbf{S}^{-1}\mathbf{A})^{-1}\mathbf{g}[(N - 1) + T^2]}. \tag{6}$$

The inner product $\mathbf{g}'\hat{\beta}$ simply picks out the estimate of the changed-level parameter from the vector $\hat{\beta}$. The quantity F given by Equation 6 follows the F distribution with 1 and $(N - 1) - (p - r)$ degrees of freedom. If the test statistic exceeds the critical value F, then the hypothesis of a treatment effect is supported.

It should be noted that the test statistic given above has an exact distribution in contrast to the test statistic given by Simonton (1977), which has only an approximate distribution. Hence, with the procedure outlined here, it is possible to control the alpha value precisely.

As noted previously, the changed-slope model discussed by Simonton (1977) is a special case of the class of models discussed by Swaminathan and Algina (1977). Since the statistical details are available in that article, only a verbal description of the analysis will be given. Again the logic of the analysis is based on Campbell's (1963) observation that if a single polynomial adequately fits the entire time-series design, then a treatment effect cannot be inferred. The steps in the Swaminathan-Algina analysis are

1. Test the adequacy of a model which specifies that the pretreatment and posttreatment portions of the series are adequately fit by separate polynomial regression curves of degree $r - 1$. Refer to this model as the complete model.

2. If the complete model is not adequate, test whether an $(r - 1)$th-degree polynomial adequately fits one portion of the time-series

design but not the other. If the answer is affirmative, then different regression curves fit the two portions of the series, and the hypothesis of a treatment effect cannot be rejected.

3. If the answer in Step 2 is negative, raise the degree of the polynomial, and repeat Steps 1 and 2. This cycle is followed until the complete model is accepted or rejected, and the answer in Step 2 is affirmative.

4. In the event the complete model is accepted, estimate the regression coefficients, and test the equality of the coefficients of the pretreatment and posttreatment portions. If the two sets of coefficients are equal, then the same curve fits both portions, and the hypothesis of a treatment effect is not tenable. If the hypothesis of equality is rejected, then the hypothesis of a treatment effect is supported.

Multiple Time-Series Design

The multiple-group time-series design consists of observing an experimental and a control group on several pretreatment occasions, introducing a treatment to the experimental group, and observing the two groups on several posttreatment occasions. In essence, Simonton's (1977) proposed analysis consists of fitting four separate first-degree polynomials: one to the pretreatment means for the experimental group, the second to the posttreatment means for the experimental group, the third to the pretreatment means for the control group, and the fourth to the posttreatment means for the control group. Inferences about treatment effects are based on statistical comparison of the slopes and the intercepts of the various equations. Again, an objection to this kind of analysis is that first-degree polynomials may not adequately fit the four sets of means. However, there is no way to detect such lack of fit from Simonton's analysis. A standard multivariate technique, profile analysis (Morrison, 1967, pp. 141–148), can be used to accomplish the aims of Simonton's analysis of the multiple-group time-series design without making the assumption that polynomials of any degree fit the data.

Simonton (1977) suggests that in an optimal situation subjects would be randomly assigned to experimental and control groups. He recognizes that this may be impossible and suggests that equality of the intercepts and slopes of the pretreatment equations for the experimental and control groups is a necessary condition for the groups to be considered equivalent. If the equality condition fails, he suggests dropping the control group and analyzing the experimental group data as an interrupted time-series experiment. In our view, a more appropriate analysis would begin by testing the hypothesis that there is no Groups × Occasions interaction. If an analysis indicates that there is no interaction, then a treatment effect is not supported. With no interaction, the mean time series for the two groups are parallel. The relationship between the mean time series remains the same over the course of the study, and therefore, it is difficult to argue that a treatment effect has occurred.

Let μ_e and μ_c denote $(px1)$ population mean vectors for the experimental and control groups, respectively. The hypothesis of no Groups × Occasions interaction can be expressed as

$$H_0:\ \mathbf{C}(\mu_e - \mu_c) = \mathbf{0}, \qquad (7)$$

where $\mathbf{0}$ is a $(px1)$ null vector and $\mathbf{C}$ is a $[(p-1)xp]$ matrix,

$$\mathbf{C} = \begin{bmatrix} 1 & -1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & -1 & \cdots & 0 & 0 \\ \cdot & \cdot & \cdot & \cdots & \cdot & \cdot \\ 0 & 0 & 0 & \cdots & 1 & -1 \end{bmatrix}.$$

It is well-known that under the assumption that the experimental and control group observations are each multinormally distributed with equal variance-covariance matrices, the hypothesis given by Equation 7 can be tested using Hotelling's T^2 statistic,

$$T^2 = \frac{N_e N_c}{N_e + N_c}(\bar{\mathbf{X}}_e - \bar{\mathbf{X}}_c)'\mathbf{C}'(\mathbf{CSC}')^{-1} \times \mathbf{C}(\bar{\mathbf{X}}_e - \bar{\mathbf{X}}_c),$$

where N_e and N_c are the numbers of cases in the experimental and control groups, $\bar{\mathbf{X}}_e$ and $\bar{\mathbf{X}}_c$ are $(px1)$ sample mean vectors, and $\mathbf{S}(pxp)$ is the pooled sample variance–covariance matrix. The test statistic can be transformed to the variate

$$F = \frac{N_e + N_c - p}{(N_e + N_c - 2)(p-1)} T^2,$$

which follows the F distribution with $p-1$ and $N_e + N_c - p$ degrees of freedom.

As indicated earlier, if the hypothesis given by Equation 7 is not rejected, the hypothesis of a treatment effect is untenable. If the hypothesis is rejected, no conclusion can be made because an interaction can occur whether or not there is a treatment effect. For example, suppose that an interaction exists for the pretreatment portion of the experimental and control group time series. Then the hypothesis given by Equation 7 should be rejected, but this hardly indicates that there is a treatment effect. Rather, it indicates that because of nonrandom assignment to groups, the mean time series would not have been parallel even if the intervention had not occurred. Now suppose that a Groups × Occasions interaction does *not* exist for the pretreatment means but does exist for the posttreatment means. Here the hypothesis given by Equation 7 should be rejected, and there is evidence supporting the hypothesis of a treatment effect, that is, that although the pretreatment mean time series were parallel, after the treatment the mean time series became nonparallel, which suggests that the treatment had some effect.

The above discussion suggests that if for the entire time series, the hypothesis of no Groups × Occasions interaction is rejected, then the next phase of analysis should determine at which point the deviation or deviations from parallelism occur: on the pretreatment occasions, on the posttreatment occasions, or on both types of occasions. If an interaction occurs only for the posttreatment occasions, then the hypothesis of a treatment effect is supported. If an interaction occurs for the pretreatment occasions, then the control group must be dropped, and the experimental group data should be analyzed as an interrupted time series experiment.

Let μ_{1e}, μ_{1c}, μ_{2e}, and μ_{2c} represent the pretreatment and posttreatment population mean vectors for the experimental and control groups, respectively. Let there be m pretreatment occasions and s posttreatment occasions. The hypothesis of no Groups × Occasions interaction for the pretreatment means may be expressed as

$$H_0\colon\ \mathbf{C}_1(\mu_{1e} - \mu_{1c}) = \mathbf{0}, \qquad (8)$$

where $\mathbf{C}_1$ has the same general form as $\mathbf{C}$ but has dimensions $[(m-1)xm]$. The relevant hypothesis for the posttreatment means may be expressed as

$$H_0\colon\ \mathbf{C}_2(\mu_{2e} - \mu_{2c}) = \mathbf{0}, \qquad (9)$$

where again $\mathbf{C}_2$ has the same general form as $\mathbf{C}$ but has dimensions $[(s-1)xs]$. The test statistics for these two hypotheses are

$$T^2{}_1 = \frac{N_eN_c}{N_e+N_c}(\bar{\mathbf{X}}_{1e} - \bar{\mathbf{X}}_{1c})'\mathbf{C}'_1(\mathbf{C}_1\mathbf{S}_1\mathbf{C}'_1)^{-1} \times \mathbf{C}_1(\bar{\mathbf{X}}_{1e} - \bar{\mathbf{X}}_{1c})$$

and

$$T^2{}_2 = \frac{N_eN_c}{N_e+N_c}(\bar{\mathbf{X}}_{2e} - \bar{\mathbf{X}}_{2c})'\mathbf{C}'_2(\mathbf{C}_2\mathbf{S}_2\mathbf{C}'_2)^{-1} \times \mathbf{C}_2(\bar{\mathbf{X}}_{2e} - \bar{\mathbf{X}}_{2c}),$$

where $\mathbf{S}_1$ and $\mathbf{S}_2$ are pooled-sample variance–covariance matrices for the pretreatment and posttreatment observations, respectively.

The test statistics can be transformed to the variates

$$F_1 = \frac{N_e + N_c - m}{(N_e + N_c - 2)(m-1)}T^2{}_1,$$

and

$$F_2 = \frac{N_e + N_c - s}{(N_e + N_c - 2)(s-1)}T^2{}_2.$$

The critical value to which F_1 and F_2 are compared is the same as the critical value to which F is compared in testing the hypothesis given by Equation 7. Using this critical value keeps the overall α rate at the nominal level. If the hypothesis given by Equation 8 is not rejected and the hypothesis given by Equation 9 is rejected, then the hypothesis of a treatment effect is supported. If only the hypothesis given by Equation 8 or both hypotheses are rejected, then the data for the experimental group is analyzed as an interrupted time-series experiment.

Discussion

The major purpose of this article was to suggest several improvements to statistical procedures reported by Simonton (1977) for the analysis of time-series designs. The improvements consist of the employment of tests of the fit of proposed models to the data and the *exact* small sample distributional

theory for testing hypotheses. In addition, it should be pointed out that the assumptions underlying the procedure advocated in this article are different from those made by Simonton. Simonton assumed that the errors, $e_1, e_2, \ldots, e_p$, follow a first-order auto-regressive scheme, that is, $e_t = \rho e_{t-1} + \delta_t$, where the residual δ_t is assumed to be independent of other δs and the es. Since N individuals are measured on p occasions ($N > p$), Simonton recommends estimating ρ for each individual (based on p observations) and pooling these estimates across the N individuals. However, when $N > p$, unless there is a strong reason to believe that the particular error structure exists, it may be more meaningful to relax this assumption, assume that the vector of errors $\mathbf{e}$ has a multivariate normal distribution with mean vector $\mathbf{0}$ and dispersion matrix Σ and proceed as suggested in this article. Another advantage of this approach is that the exact distributions of the statistics for testing hypotheses of interest are known (as compared with the Simonton approach in which only the approximate distribution of the test statistic is known).

A necessary condition for the application of the procedures developed in this article is that the number of subjects exceed the number of occasions. Simonton tacitly assumed this condition also. This does not seem to be a serious drawback, since with a large number of subjects, fewer time points are required for satisfactory estimation of parameters. When $N < p$, a structure has to be imposed on $\mathbf{e}$. The procedure suggested by Simonton is more appropriate in this case. However, even in this case, the test of the fit of the model to the data should be explored. This is not a trivial problem but may be solved by adapting methods such as those suggested by Krishnaiah and Murthy (1966) and Rao (1967).

If one of the changed-level models fits the data, and a treatment effect has occurred, then the Swaminathan-Algina (1977) analysis should detect this treatment effect because the changed-level models state that a polynomial fits the pretreatment data, whereas a polynominal does not fit the posttreatment data. Hence, Step 2 of the Swaminathan-Algina analysis should indicate a treatment effect. Are the changed-level models then superfluous? In our opinion, they are not. The Swaminathan-Algina analysis asks whether the pretreatment and posttreatment regression curves on time are the same. An affirmative answer strongly indicates that a treatment effect has not occurred. A negative answer indicates that after the treatment occurred, the regression curve shifted. There may be numerous threats to internal validity that provide reasonable explanations of the shift, and the evidence for a treatment effect may be quite weak. The changed-level models postulate the form of the treatment effect. If the changed-level model fits the data and the changed-level parameter is nonzero, then the class of threats to internal validity that are plausible explanations of the form of the regression curve will probably be narrower. Hence, employing the changed-level models as suggested by Simonton with the analytic procedure advocated in this article would provide an efficient method for the analysis of the interrupted time-series designs.

In the Introduction it was noted that if the residuals are correlated, then the ordinary least squares estimator may not be efficient. Rao (1967) has discussed the situations in which the ordinary least squares estimator is more efficient than the modified generalized least squares estimator. However, strictly speaking, application of his results requires knowledge of the structure of Σ. Furthermore, even when ordinary least squares estimators are more efficient, it can be shown that multivariate procedures should be used for testing hypotheses about the adequacy of the model and about β (Grizzle & Allen, 1969).

Reply to Algina and Swaminathan

Dean Keith Simonton
University of California, Davis

Algina and Swaminathan have proposed more sophisticated analyses for the cross-sectional time-series experiment. Especially valuable is their suggested procedure for testing the empirical adequacy of the hypothesized intervention model. Nonetheless, the greater complexity of their approach may not always be justified in many research applications. In particular, their exact-test method will normally yield statistical inferences similar to those of my approximate-test procedure.

Algina and Swaminathan's (1979) article constitutes a significant contribution to the recent literature on cross-sectional time-series quasi-experiments. Certainly they have offered some reasonable and more sophisticated alternatives to the analyses I had proposed in an earlier article (Simonton, 1977). Particularly notable, in my view, are the procedures they have developed for testing the adequacy of a model's fit to the data, an issue I neglected. Although it may not always be necessary to run such tests, it is easy to imagine many real situations in which such verification would be required. On the other hand, the general analytical procedure they have outlined for parameter estimation and significance tests is definitely more complicated than that I had proposed. Therefore, it is reasonable to ask what specific advantages accrue from such augmented complexity. Apparently, the chief improvements are two in number. In the first place, the significance tests that they have developed are exact, whereas mine are only approximate. Whether one prefers complex exact tests or simple approximate tests may be somewhat a matter of personal choice, at least given our ignorance regarding the degree of approximation in the approximate tests. Also, the exact tests are only exact when the assumptions are exactly met, and hence the distinction is partially obscured.

Requests for reprints should be sent to Dean Keith Simonton, Department of Psychology, University of California, Davis, California 95616.

However, Algina and Swaminathan raise a second and related critical point about their proposed alternative: My solution to the serial dependencies in the disturbances was to postulate a first-order autoregressive scheme, whereas they estimate a variance–covariance matrix without any a priori structure. As they point out, their procedure requires that the number of subjects exceed the number of observations, but this condition is easily fulfilled. Furthermore, they mention situations in which a first-order autoregressive model may not adequately describe the disturbance process (e.g., when there is measurement error). Nonetheless, I think it is reasonable to ask what the consequences of following my procedure are anyway, no matter what defines the true variance–covariance matrix. Here I believe the differences between the two alternative procedures will usually be small. For example, if the disturbances actually are generated by a second-order autoregressive scheme, the significance tests will be only slightly affected (Miklich, Note 1), whereas the chief loss will fall in the area of estimation efficiency (Engle, 1974). Yet at this point in the history of the behavioral sciences, estimation efficiency (i.e., the variance of our parameter estimates) is probably a low priority concern. Moreover, whenever we are dealing with quasi-experiments entailing only one intervention, the significance tests for cross-sectional time series are extremely robust, even when the autoregression is moderate (Miklich, Note 1). Indeed, it is my belief

that most cross-sectional time-series experiments could probably do without generalized least squares estimation and could simply rely on a more conservative alpha level (e.g., minimum of .01).

In all, I am fairly confident that in the majority of data analysis situations, it may not make a substantial difference whether one employs my simple approximate-test approach with an a priori disturbance model or the Algina-Swaminathan complex exact-test approach with an a posteriori variance–covariance matrix. Nevertheless, I am also of the opinion that their procedures represent a wider range of valuable tests that probably render their approach far more useful in the long run as a general strategy for analyzing such data.

The MMPI As a Primary Differentiator and Predictor of Behavior in Prison: A Methodological Critique and Review of the Recent Literature

Milton L. Gearing II
University of South Carolina

Seventy-one investigations of Minnesota Multiphasic Personality Inventory (MMPI) usage in prison work were systematically evaluated. Additional studies were examined to provide a methodological basis for the comparisons of the research, which were made within sections on sampling procedures, sources of variance and their effects on test results, protocol validity, and methods of profile interpretation. Several methodological shortcomings and various differences in procedure across studies limit the generalizability of the findings. However, research in the hostile-assaultive section has produced preliminary MMPI indicators for a type of violently aggressive behavior pattern that is otherwise difficult to detect. Other areas in which the MMPI shows promise include homosexuality, recidivism, and the classification of psychopathologic behavior. More research is needed in the areas of institutional adjustment and suicide. Recommendations for future investigations prescribe adequately controlled sampling procedures, modifications in the interpretation of protocol validity, investigation of certain methodological questions in their own right, consideration of more than one aspect of profile data, the use of base-rate probabilities in predictive studies, and the pursuit of longitudinal studies with thorough follow-up procedures.

The Minnesota Multiphasic Personality Inventory (MMPI) is probably the most widely used personality test in American criminal justice settings today, and MMPI administration is a part of standard admissions practice for all federal institutions as well as for several state and local institutions (Elion & Megargee, 1975). It is routinely used as a general aid in diagnosis and treatment program planning (Haven, Note 1), yet several researchers have investigated more specific applications of the MMPI that deal with several varieties of circumscribed inmate behavioral problems. These investigators are striving to increase the usefulness of the MMPI in prison settings, either for gaining dynamic insights into a specific behavior problem group or for probabilistic prediction of future behavior problems. The full extent of the MMPI's present usefulness and its potential in these two major applications constitutes the focus of the present review. An attempt is made to determine if the MMPI has the potential to become a major and valuable aid in the making of correctional decisions that are appropriate and beneficial for the individual inmate's welfare as well as facilitative of the smooth and effective operation of prison programs in general.

The MMPI consists of 550 different statements covering a wide range of subject mat-

The author gratefully acknowledges the repeated correspondence of James H. Panton and Edwin I. Megargee, whose generous assistance in supplying information undoubtedly improved the quality of this review. The author also acknowledges the helpful correspondence of Paul Gendreau, Thomas E. Hannum, and David M. Pierce.

The author would like to thank Herman Salzberg for his extremely helpful suggestions and Will Drennen and Alexander Galvin for their comments.

Requests for reprints should be sent to Milton L. Gearing II, who is now at the Department of Psychiatry, Division of Psychology, University of Texas Health Science Center at Dallas, 5323 Harry Hines Boulevard, Dallas, Texas 75235.

Table 1
Standard Validity and Clinical Scales for the Minnesota Multiphasic Personality Inventory

Symbol	Scale
?	Question
L	Lie
F	Validity
K	Test-Taking Attitude
Hs(1)	Hypochondriasis
D(2)	Depression
Hy(3)	Hysteria
Pd(4)	Psychopathic Deviate
Mf(5)	Masculinity–Femininity
Pa(6)	Paranoia
Pt(7)	Psychasthenia
Sc(8)	Schizophrenia
Ma(9)	Hypomania
Si(0)	Social Introversion

ter. The client responds to each statement by answering *true* or *false* or leaving the statement blank. The standard MMPI profile consists of 4 validity scales (*?, L, F,* and *K*) and 10 clinical scales (*Hs, D, Hy, Pd, Mf, Pa, Pt, Sc, Ma,* and *Si*). The *?* (Question) scale merely records the number of items left blank. The *L* (Lie) scale consists of 15 statements describing minor yet common human failings that attempt to identify intentional efforts by the subject to make himself or herself "look good." The *F* (Validity) scale contains 64 items rarely answered in the scorable direction by normals, and it attempts to detect the presence of confusion due to psychosis or illiteracy, a look-bad attempt meant as a "cry for help" or a random response pattern. The *K* (Test-Taking Attitude) scale consists of 30 items and basically serves as a measure of defensiveness in the subject's test-taking attitude. The *Hs* (Hypochondriasis) scale has 33 items reflecting somatic complaints commonly found in hypochondriasis. The *D* (Depression) scale contains 60 items that describe various symptoms of depression, such as feelings of hopelessness and worthlessness, preoccupation with death, and so forth. The *Hy* (Hysteria) scale is made up of 60 items that tend to identify conversion hysterics in particular. The *Pd* (Psychopathic Deviate) scale is comprised of 50 items designed to detect the amoral and asocial types commonly described as psychopathic personality disorders. The *Mf* (Masculinity–Femininity) scale has 60 items and was initially designed to identify those effeminate males suffering from a sexual inversion disorder but actually seems to reflect aesthetic and vocational interests. The *Pa* (Paranoia) scale contains 40 items intended to detect the clinical pattern of paranoia, which may also be part of another disorder such as schizophrenia. The *Pt* (Psychasthenia) scale is made up of 48 items that attempt to detect the obsessive–compulsive syndrome and that are also suggestive of a high degree of anxiety. The *Sc* (Schizophrenia) scale consists of 78 items that were originally intended to differentiate the psychotic pattern of schizophrenia. The *Ma* (Hypomania) scale contains 46 items that reflect the overactivity, emotional excitement, and flight of ideas common to the affective disorder of hypomania. Finally, the *Si* (Social Introversion) scale is made up of 70 items suggesting unease in social situations, hypersensitivity, and insecurity. The 10 clinical scales are also commonly referred to by number. (See Table 1 for the symbols, numbers, and names of the standard MMPI scales.)

Recently Megargee and his associates (Megargee, 1977a; Megargee, 1977b; Megargee & Bohn, 1977; Megargee & Dorhout, 1977; Meyer & Megargee, 1977) filled an entire issue of *Criminal Justice and Behavior* with the results of 6 years of coordinated research. This research was aimed at the derivation of a comprehensive MMPI classification system for criminal behavior. Megargee (1977a) makes a compelling case for the economy, efficiency, reliability, validity, and operational utility of such a system by comparing it to existing systems on seven dimensions of usefulness that he feels are requirements for productive classification. He then formulates 8 research questions that he asserts must all be answered in the affirmative if the MMPI is to be an adequate basis for a typological system, and he explains how their series of research studies was designed to address these questions. This series of studies has yielded 10 reliably occurring MMPI profile configurations in a population

of youthful male federal offenders. Each profile type is presented with rules for inclusion into its respective classification, modal descriptions of significant characteristics drawn from several assessment sources and case history data, and hypotheses about optimal modes of management and treatment. This computer-assisted system successfully classified 96% of their sample of 1,214 offenders. Although these results are represented as a "progress report," these researchers feel that

> thus far, the taxonomy has surpassed all of our initial expectations. The system has outgrown the capability of one laboratory to investigate it adequately. It is hoped that this series of progress reports will stimulate other researchers to investigate these groups and help us determine their utility. (Megargee, 1977a, p. 113)

Six of the eight questions mentioned above were addressed and have been answered in the affirmative, and this massive research effort continues. Besides seeking replication with other prison populations and in other areas of the country, Megargee and his associates are interested in productively interfacing their fledgling empirical system with both theoretical orientations and other empirical lines of research in corrections (Megargee, 1977b). Their initial results appear promising.

This review focuses on research that has differentiated criterion and comparison inmate groups on some independent basis and has then sought MMPI indicators that reliably differentiate these groups. It is hoped that this will be a useful complement to the work of Megargee and his associates, who are separating inmate groups on the basis of their MMPI profiles and then seeking corresponding dynamic and predictive behavioral indicators. Haven (Note 1) has comprehensively reviewed earlier literature in this area, but a substantial body of research has emerged since his investigation (see Dahlstrom, Welsh, & Dahlstrom, 1975, chap. 3). An up-to-date assessment of the MMPI's potential in prison work is called for, both to stimulate relevant cross-validations and extensions of the latest findings and to maximize the productive interfacing of these findings with the important work of Megargee and his associates. Studies published in English-language journals from 1967 to the time of Megargee et al.'s (Megargee, 1977a; Megargee, 1977b; Megargee & Bohn, 1977; Megargee & Dorhout, 1977; Meyer & Megargee, 1977) publications are emphasized, but studies published before 1967 that meet certain specific criteria (see the last paragraph of the Protocol Validity subsection) are included for the sake of representativeness and continuity. Only studies using some version of the MMPI that at least provides for full scoring of the 13 standard scales are included; Mini-Mult (Kincannon's, 1968, 71-item short form of the MMPI that estimates scores on most of the standard scales) prison research is not addressed. The Review section itself is limited to research that deals with civilian criminal populations incarcerated in conventional correctional facilities or psychiatric facilities specifically for the criminally insane. All criterion and comparison groups are drawn from such populations unless otherwise noted. Research dealing with incarcerated armed services populations, probation populations, and psychopathic/sociopathic populations in conventional mental hospitals is not included.

The first section of this review consists of a methodological evaluation of the research that includes the following subsections: Sampling Procedures, Sources of Variance and Their Effects on Test Results, Protocol Validity, and Methods of Profile Interpretation. Limitations of the research are discussed, and recommendations for standard design modifications and further needed investigations are presented. The studies are then reviewed under two major categories: The MMPI As a Primary Differentiator of Deviant Behavior and The MMPI As a Predictor of Deviant Behavior. A third section, MMPI Differences Across Race and Sex, examines the effects these two variables have on MMPI profiles obtained from prisoners and examines the implications for interpretation and generalization.

Methodological Evaluation

The studies reviewed in this article illustrate several methodological shortcomings.

[a] V = validity criteria: 1 = no criteria employed; 2 = employed standard cutoffs (*L* scale *T* score maximum of 70, *F* scale *T* score maximum of 80, *K* scale *T* score maximum of 70) or discarded invalid Minnesota Multiphasic Personality Inventories (MMPIs); 3 = detected and discarded random profiles only.
[b] S = sampling procedures: R = complete randomization; M = complete matching; r = partial randomization; m = partial matching; $\frac{r}{M}$ = mixed approach; more than one pair of criterion and comparison groups used.
[c] T = timing of MMPI administration: a = routine admissions administration; s = given specifically for the study conducted; d = administered just prior to discharge; ? = not specified; $\frac{a}{s}$ = mixed approach, more than one pair of criterion and comparison groups used.
[d] Those characteristics either controlled or matched: 1 = addiction status; 2 = age; 3 = educational achievement; 4 = ethnicity; 5 = IQ; 6 = length of current sentence; 7 = length of time in prison; 8 = marital status; 9 = number of prior convictions; 10 = number of disciplinary restrictions; 11 = race; 12 = rate of recidivism; 13 = religion; 14 = sex; 15 = social class; 16 = socioeconomic status.
[e] Conducted preliminary IQ/reading-level screening.

In addition to the problems discussed later, the studies vary on such dimensions as timing of administration of the MMPI (i.e., on admission vs. at the time of the research study), security grade of the institution from which the test groups were drawn (this was frequently not specified) and region of the country in which the study was conducted. Table 2 presents most of the important characteristics of the studies reviewed, and the lack of consistency with respect to the control of subject characteristics across the studies is readily apparent. Overall, the variations in procedure substantially limit the generalizability of present results.

Sampling Procedures

Slightly more than half of the studies used some form of matching (i.e., matching on a few dimensions such as age, length of imprisonment, IQ, or educational level) or random sampling, whereas the rest used every available member of a group with completed MMPIs. Those studies employing partial randomization frequently used ran-

domly selected comparison groups while using all available prisoners who qualified for the criterion group. Studies employing partial matching commonly had more than two groups within an experimental comparison or more than one comparison and only matched some of their groups on a few dimensions, such as those mentioned above. (See Table 2 for all of the dimensions that were employed.)

Although complete randomization in prison research is sometimes impractical, partial approaches such as those above do not compensate for systematic bias. If full randomization cannot be realized, then matching a comparison group to the available criterion group (which is defined by a history of a given target behavior such as escapism, homosexuality, etc.) is preferable to randomizing the comparison group, since the latter procedure does not constitute an intelligible comparison. Partial matching approaches have often been necessitated by the lack of data on some matched variables for certain groups, yet this still serves to weaken the representativeness of results. In short, the findings of many studies are severely limited in their generalizability and must be interpreted with caution.

Sources of Variance and Their Effects on Test Results

Table 2 demonstrates that the only source of variance that was consistently controlled across almost all studies was sex. Sixty-nine studies limited their observations to only one sex, and the overwhelming majority investigated male prisoners. The only other sources of variance that were controlled by a substantial number of studies were age, educational achievement, IQ, and race.

Some research has been done on the effects of these latter variables on MMPI profiles in general. Costello, Tiffany, and Grier (1972) examined several methodological questions with respect to racial (i.e., black–white) comparisons in their investigation of carefully matched inpatient and outpatient psychiatric clients. They found that blacks had more elevated profiles in general, with significantly higher scores on the *F*, *Hs*, *Mf*, *Sc*, and *Ma* scales and significantly lower scores on the *K* scale. Gynther (1972) reviewed the literature on black–white MMPI differences in normal populations and reached several pertinent conclusions. There seem to be consistent differences between blacks' and whites' MMPIs, the most frequent being significantly higher elevations for blacks on the *Sc* and *Ma* scales, which seem to be affected by such variables as education, residence, and cultural separation. However, Gynther claims that there is no evidence to indicate that these trends signify that blacks are less well adjusted than whites. Gynther advocates the construction of a new MMPI form with *T* scores based on black norms and with the derivation of black behavioral correlates based on profile types. He suggests that a temporary solution would be the generation of qualifying rules for the interpretation of blacks' MMPIs, and he urges that those interpreting MMPIs should be alerted to the potential misuse of the test in treating black profiles in the same manner as white profiles.

Subsequent research has attempted to clarify the issues raised by Gynther's (1972) review. Gynther, Altman, and Warbin (1973) investigated the consistent finding of higher *F* scale scores for blacks by comparing the MMPIs of 1,125 white psychiatric inpatients to those of 134 black psychiatric inpatients (63% of the overall sample was male). They also used records that contained sets of 168 demographic descriptors and 111 mental status items for each patient. Nonrandom profiles having an *F* scale raw score $\geqslant 26$ were separated from the other profiles for each racial group, and the demographic and mental status items were analyzed for their ability to differentiate the groups. Replications were carried out for both black and white groups. For whites, 16 items overall provided significant differentiations across the original and replication samples, and these items essentially characterized *F* scale $\geqslant 26$ profiles as representing "confused psychotics." This was consistent with earlier research findings. However, the original black sample with *F* scale $\geqslant 26$ profiles shared only 5 discriminating items with the original white sample, and only 3 of these items were scored

in the same direction. Furthermore, not one variable provided a significant differentiation for both the original and replication samples of blacks. Gynther et al. (1973) concluded that blacks with an *F* scale score $\geqslant 26$ are not seen any differently than blacks with lower *F* scale scores when compared on a mental status exam, and they maintain that an *F* scale score $\geqslant 26$ for a black psychiatric patient has different behavioral correlates than a similar score for a white psychiatric patient. They also suggest that this difference may be due to "race-sensitive" items on the MMPI; blacks seemed to favor items reflecting certain attitudinal dispositions such as alienation, religiousness, liking for school, and romanticism.

As part of a larger project, Gynther, Lachar, and Dahlstrom (1978) used a large sample of normal, conservative middle-class black adults from Alabama, Michigan, and North Carolina (321 males, 561 females) to generate a new *F* scale for blacks. They replicated the criterion used when the original *F* scale was generated on a Minnesota sample, which accepted items answered in a given direction by 10% or less of the sample. They identified a total of 33 items in this manner, 22 of which are on the standard 64-item *F* scale. They found that higher scores in their black sample for both the original and the new *F* scale were significantly related to a younger age, less education, and a less-skilled job classification of the head of the household. Gynther et al. (1978) concluded that the significant correlates of high *F* scale scores for whites do not appear to be valid for blacks, and they suggest that their new *F* scale may be a better measure of deviant responding for blacks than the standard *F* scale.

Further studies have investigated other MMPI scales as well in their examination of racial differences on the test. Penk and Robinowitz (1974) investigated the profiles of black and white male veterans who were drug abusers. They compared black opiate users to white opiate users as well as comparing black opiate users to white opiate nonusers. They found that black opiate users scored significantly lower than white opiate users on the *F* and *Hy* scales and scored lower than white non-opiate users on the *F*, *Pt*, *Sc*, and *Si* scales. They note that these findings conflict with the expectation that blacks typically obtain higher MMPI scale scores.

Davis and Jones (1974) compared black and white veterans who were psychiatric patients by systematically varying race, education, and differential diagnoses obtained independently from the MMPIs. An initial survey of all available black subjects (390) and of a randomly selected white comparison group found that blacks were more likely to be diagnosed schizophrenic, whereas whites were more likely to be diagnosed alcoholic and/or depressed. They concluded that there seem to be race-related differences in diagnosis, but they were unable to determine whether this was due to actual race-related variations in psychopathology or to blacks being misdiagnosed more often. Next, Davis and Jones randomly selected 20 subjects for each of eight groups; each racial group was blocked into groups of high-education (minimum of 12 years of education) schizophrenics, low-education schizophrenics, high-education nonschizophrenics, and low-education nonschizophrenics. Subjects older than 50 or having an *F-K* index greater than 14 were not included. They found that there was no significant main effects associated with differences in race. Schizophrenics scored significantly higher on the *Pa* and *Sc* scales than nonschizophrenics, and the poorly educated scored significantly higher on the *Sc* scale than the well educated. Some interaction effects were evident: The more poorly educated blacks and better educated whites scored significantly higher on the *Pa* scale than the other subjects, and the more poorly educated blacks scored significantly higher on the *Sc* scale than the other subjects (with the better educated blacks scoring the lowest on this scale). Davis and Jones concluded that race is a type of independent subject variable that confounds attempts to adequately interpret MMPI profiles of randomly selected black versus white groups, but this is *not* the case when diagnosis and education are controlled. They maintained that with poorly educated groups or with randomly selected groups in which the majority of blacks are poorly educated, blacks would be

expected to perform in a more pathological direction than most random samples of whites who are similar in characteristics, such as type of psychopathology.

Cowan, Watkins, and Davis (1975) examined the same subjects used by Davis and Jones (1974) and blindly sorted the MMPI profiles into schizophrenic and nonschizophrenic groups. A protocol was classified as schizophrenic if the *Sc* scale *T* score exceeded 70 and if the *Sc* scale was more elevated than the *Pt* scale. In three of the four nonschizophrenic groups, the profiles were correctly classified significantly more often than by chance in a way that conformed to previously determined expectations for percentage of correct classification. However, almost one half (9 out of 20) of the poorly educated black nonschizophrenics were misclassified as schizophrenic. Cowan et al. concluded that although cultural background factors exert a significant influence, much of the reported variation in blacks' MMPIs may be a function of education. They maintained that the MMPI appears to retain adequate discriminative power for blacks with at least 12 years of education.

The conclusions of Davis and Jones (1974) and Cowan et al. (1975) seem to constitute the key issue here. Davis and Jones suggest that their results indirectly support Gynther's (1972) hypothesis, which maintained that blacks produce more apparently pathological MMPIs because of their experiences of alienation from the established white society. Gynther maintains that blacks learn to be suspicious of others because it is necessary for their survival in this society. However, Davis and Jones point out that well-educated blacks do not appear to demonstrate the consistent racial differences on MMPI scales that randomly selected groups of blacks do, and they conclude that a more advanced education seems to have either a masking or obliterating effect on cultural factors that can produce misleading MMPI configurations. They hypothesized that a selection process may be operating here in which the more sensitive and suspicious blacks drop out of school as soon as they are legally allowed to. On the other hand, blacks that elect to continue their education are exposed to extended culturation effects through their prolonged contact with white values and expectations, and since they are less sensitive and suspicious than those blacks who drop out, they are more apt to assimilate the cultural values of whites. Cowan et al. essentially concur with this perspective. Therefore, if higher elevations for blacks on MMPI scales are chiefly due to factors such as differences in IQ or education instead of race, then Gynther's advocacy of separate norms for blacks seems inappropriate. Apparent bias could be due to a combination of factors in which race may play a minor role. At this point the assumption of racial bias of the MMPI appears to be premature at best; the entire issue demands further research. (See the discussion of racial differences in MMPI profiles of prisoners in particular, which is included near the end of the Review section.)

Panton (1960a) has investigated the effects of intelligence on profiles taken from a prison population. Prisoners with an IQ below 110 consistently demonstrated neuroticism and anxiety (elevations on the *Hs*, *D*, *Pt*, and *Sc* scales), whereas prisoners above the 110 cutoff consistently demonstrated character disorders (elevations on the *Hy*, *Pd*, and *Ma* scales). Panton (1959a) also examined the effects of age on prison profiles and found that white inmates over 30 years old scored significantly higher than under-30 white inmates on the *Hs*, *D*, *Hy*, and *Pd* scales and significantly lower on the *Sc*, *Ma*, and *Si* scales. (Groups of black inmates did not show these differences.) A second study by Panton (1976–1977) on the effects of age found that when compared to baseline MMPI figures for the prison population, inmates who were at least 60 years old displayed "a neurotic overlay with less psychopathy" (significantly higher on the *Hs*, *D*, *Hy*, and *Si* scales and significantly lower on the *Pd* scale). In their investigation of the *F* scale in white psychiatric patients, Gynther and Shimkunas (1965a; see the section on Protocol Validity) found an interaction between age and intelligence that affected *F* scale scores.

These findings are far from conclusive, but they do suggest that all of these factors are

primary sources of variance that should be controlled in MMPI research. In fact, they demand further investigation in their own right (especially the issue of racial and cultural bias), but until the nature of their influence is clarified, they should be dealt with either through matching or blocking procedures. Even researchers using full randomized assignment would be well-advised to examine their samples post hoc for significant differences on age, IQ, and race. Other variables in Table 2 that are more specific to prison populations have not been investigated for their effects on MMPI protocols. Therefore, randomization seems to be the preferred method to control for confounding effects, since these latter potential sources of variance may exert a presently unknown influence on test results.

Protocol Validity

Hathaway and McKinley (1967) state that "subjects sixteen years of age or older with at least six years of successful schooling can be expected to complete the MMPI without difficulty" (p. 9). Yet only eight of the studies reviewed (see Table 2) mentioned any attempts to screen their subjects for IQ or reading level, even though there is a significant incidence of illiterate and foreign-language-speaking inmates in prison in general. Such preliminary screening is an important consideration in obtaining valid profiles and should be a standard part of MMPI research in prisons. Dahlstrom, Welsh, and Dahlstrom (1972) recommend the use of brief intellective or reading achievement measures such as the Wide Range Achievement Test (Jastak, Bijou, & Jastak, 1965), the Ohio Literacy Test (Foster & Goddard, 1924), or the Kent EGY (Kent, 1946) to identify subjects who may have difficulty completing the MMPI (p. 21). However, they report one study (Glenn, 1949) that investigated the use of oral presentation of the MMPI to some retarded juvenile delinquents who lacked the above minimal educational requirements. This study concluded that success could be achieved for subjects with an IQ of at least 65 and with at least 3 years of schooling.

Dahlstrom et al. (1972) also report that Panton has adopted an oral delivery approach for the group testing of prisoners in which the inmate with the most education and best reading competency reads the items to the rest of the group. The extent to which this procedure is legitimate with respect to those prisoners below the IQ/reading-level criteria has not been investigated. Therefore, at this time the use of the MMPI with prisoners failing to meet these criteria cannot be sanctioned as a sound methodological practice. Further research should investigate the advisability of oral administration with prisoners having less than a sixth-grade reading level or an IQ below 80 (the common Wechsler Adult Intelligence Scale [WAIS] cutoff; see Dahlstrom et al., 1972, p. 21). One alternative for researchers whose sample representativeness is threatened by this requirement would be to administer oral versions of the MMPI to the subjects in question and analyze their overall outcome data twice, once by including these subjects and once by excluding them from the analysis. Differences in results could then be examined, and unless the number of such oral administrations is substantial, few if any significant differences in outcome between the two analyses should be found.

One study links the validity of a given MMPI profile with the timing of its administration in the prison setting. Pierce (1972a) gave 60 inmates the MMPI on their admission to prison and then retested the same group 6 weeks later. He found that group mean scores dropped significantly on the *Pt*, *Sc*, and *Si* scales, whereas the group mean score rose significantly on the *K* scale. He concluded that the initial profiles were confounded by the presence of stress associated with entering prison, and this tended to obscure the actual profile configuration that was indicative of the inmate's true personality. Although comparisons of changes within an individual inmate's two profiles would have been preferable to Pierce's method of comparing differences between the group means for each scale, Pierce has raised an important question here. Further research should determine whether the delaying of MMPI administration to allow

for some institutional adjustment and a corresponding decrease of situational stress would result in more accurate and more useful MMPI profiles.

The *F* scale is probably the single most widely used indicator of MMPI profile invalidity. A common contemporary practice is to discard profiles with *T* scores exceeding 70 for the *L* scale, 80 for the *F* scale, or 70 for the *K* scale, and a high *F* scale score is usually the criterion that causes the discarding of protocols. As shown by Table 2, 29 of the previously mentioned studies deal with this protocol validity question in some manner, whereas the rest seem to ignore the issue entirely. However, research suggests that the rigid application of the *F* scale *T* score exceeding 80 to determine invalidity may be ill-advised. Comrey's (1957–1958) factor analysis of the *F* scale led him to conclude that a high *F* scale score may be a valid indicator of pathology, not a signal of profile invalidity. Morrice (1957) felt that high *F* scale scores were an index of personality disorder in his group of recidivist criminals, and he suggested focusing on overall profile configurations as meaningful while underinterpreting absolute single scale elevations. He reports the following "impressionistic" investigative results:

> The test was repeated in three fully investigated prisoners to determine whether their profiles were reproducible. In fact the test, repeated after an interval of six to seven months, reproduced the original profiles very closely and in each case with a repeat of an abnormally high *F* score. There was no reason for these three prisoners to malinger and it would be clever deception indeed to reproduce nearly identical responses . . . . The impression gained is that a high *F*, together with several abnormal scores on the personality scales, is meaningful in terms of personality disorder of antisocial type. (Morrice, 1957, p. 634)

This latter study was the first suggestion that people specifically classified as character disorders may validly produce high *F* scale scores when they respond to the test in a candid and truthful manner. In their consideration of the meaning of the *F* scale, Dahlstrom et al. (1972) concluded that in certain instances, "elevated *F* scale scores are part and parcel of the behavioral disorder generating the clinical-scale configuration, documenting its range and severity but not reflecting adversely upon the dependability of the MMPI protocol itself" (p. 161; see this source for a more in-depth consideration of the *F* scale). They even suggest that valid profiles may, in "rare instances," exhibit raw-score *F* scale values of 40 or more (*T* score well over 110) for these very reasons.

Later studies supporting the validity of nonrandom profiles with *F* scale *T* scores exceeding 80 have searched for possible clinical interpretations of the high *F* scale score. Gynther (1961) found evidence which suggested that *F* scale scores could differentiate between diagnostic classifications, since his group of "aggressive" criminals tended to get *T* scores exceeding 80 significantly more often than "passive" criminals. Investigating *F* scale scores with respect to 12 crime classification groups, Gynther (1962) also found a significant relationship between high *F* scale scores and sexual crimes and concluded that larger *F* scale values indicate "emotionally 'sicker'" criminals. Blumberg (1967) found supporting evidence for Gynther's (1962) conclusion. However, Gauron, Stevenson, and Englehart (1962) failed to differentiate behavioral disorders from the rest of their hospital patient sample on the basis of high *F* scale scores and concluded that an *F* scale *T* score exceeding 80 "cannot be routinely employed as a diagnostic sign of behavior disorder with psychiatric patients" (p. 488). Gynther and Shimkunas (1965b) attempted to confirm these findings by using both hospital patient and prisoner groups. Their psychotic patients accounted for almost 70% of their *F* scale *T* scores that exceeded 80 for the patient group, whereas their behavior disorder prisoners accounted for 66% of their *F* scale *T* scores that exceeded 80 for the prisoner group. The reversal of this relationship between high *F* scale scores and diagnosis was significant at the .001 level of confidence. They concluded that the differences between the two samples reflect personality features of those who break the law, and they concur with Leary's (cited in Gynther & Shimkunas, 1965b) assertion that the *F* scale measures hostility and aggression. Rice (1968) also found a

significant relationship between *F* scale *T* scores that exceeded 80 and overtly hostile, aggressive behavior.

A few studies have attempted to derive diagnostic indicators from the *F* scale. McKegney (1965) found that 21 specific *F* scale items were answered in the scorable direction by male juvenile delinquents significantly more frequently than by normals. He concluded that these items accurately described special problem areas of the subjects in his sample even though they caused *F* scale *T* scores above 80, and he suggested that specific *F* scale item endorsements could provide clinical insight into individual cases. Dahlstrom et al. (1972) echo this suggestion, pointing out that 21 *F* scale items appear on Grayson's Critical Items List (Grayson, Note 2) and stating that "in the utilization of the *F* scale items as a set of rare answers, the clinician should not lose sight of the possibility that one or all of the answers to these items from some test subjects may be quite literally true, clinically relevant, and worthy of special investigation" (p. 115). Gynther and Petzel (1967) failed to confirm their hypothesis that psychotics and individuals with behavioral disorders with *F* scale *T* scores exceeding 80 endorse different patterns of *F* scale items; only one item (No. 215, "I have used alcohol excessively") reliably differentiated the two groups. However, using this one item in conjunction with the total number of items endorsed on a 12-item *F* scale subscale of manifest psychotic content proved to effectively differentiate the two groups. They suggest that a "nonconformity" dimension causes high *F* scale scores and is a general dimension underlying both psychosis and behavior disorders.

The effects of age and intelligence on *F* scale scores in psychiatric patients were investigated by Gynther and Shimkunas (1965a). Several of the above studies have found that youth correlated with higher *F* scale scores (Blumberg, 1967; Gauron et al., 1962; Gynther, 1961; Gynther, 1962), but no consistent relationship was found between high *F* scale scores and intelligence (Gynther, 1961; Gynther, 1962) or educational level (Gauron et al., 1962; McKegney, 1965). Gynther and Shimkunas (1965a) found an interaction between age and intelligence that they termed the "critical element" affecting changes in *F* scale scores: The scores decreased with increasing age for low- and high-IQ subjects but remained relatively constant for average-IQ subjects. However, educational level did not effect *F* scale scores.

A few studies have examined other indices of invalid MMPI profiles with prisoners. Lawton and Kleban (1965) retested their prisoner group with the MMPI and told them to simulate someone who had never been in trouble with the law. Seven clinical scales showed significant drops compared to the original testing, but relative configurational elevations did not change significantly. Lawton and Kleban concluded that prisoners are unable to successfully manipulate the *Pd* scale alone to conceal their sociopathy. Bennett (1970) used a similar design and concluded that inmates either cannot or do not "fake good" to any significant degree. However, Gendreau, Irvine, and Knight (1973) criticized the above instructional sets as unrealistic and after obtaining protocols in the standard fashion, instructed their prisoners to successively fake bad and fake good on retests as if they were trying to manipulate the prison system for desired treatment or privileges. They found that faking in both directions radically distorted initial profiles and successfully concealed the basic characterological problems of the prisoners. Both the *F* scale (using a raw score cutoff of 34, which has a *T* score well over 100) and the *F-K* index (subtracting the *K* scale score from the *F* scale raw score and using a cutoff of 24) successfully separated 100% of the fake-bad profiles from the original standard administration profiles. All seven of the indicators that they examined effectively identified fake-good profiles, the two best indicators being the Positive Malingering (*Mp*) scale (92% overall hit rate) of Cofer, Chance, and Judson (cited in Dahlstrom et al., 1972) and the *F-K* index (85% hit rate). Ability to fake effectively was not found to be related to IQ. Gendreau et al. advocated further research investigating the readjustment of the standard *F* scale and

F-K index cutoff scores to properly discriminate honest versus faked inmate profiles and suggested the possibility of the routine use of the *Mp* scale in identifying fake-good profiles.

As part of their larger study investigating racial differences on the MMPI, Costello et al. (1972) considered the effects that different validity criteria for the selection of protocols have on research outcomes. Their study analyzed the data by using all available protocols and then reanalyzed the data by using only valid protocols (*?* scale maximum *T* score of 100, *L* scale maximum *T* score of 70, *F* scale maximum *T* score of 80, *K* scale maximum *T* score of 70, *F-K* maximum raw score of 9). They found that all significant differences in the initial analysis were eliminated in the reanalysis, and they felt that this was partially due to the fact that high *F* scale scores are associated with elevations on certain clinical scales (such as the *Sc* scale). They concluded that the employment of validity criteria similar to those described above restricted both profile variability and the detection of actual differences between groups. (They also noted that more black profiles were eliminated by those criteria than white profiles.)

The above studies offer several insights into what constitutes a valid MMPI inmate profile. Of primary importance is the finding that the conventional cutoff of the *F* scale *T* score exceeding 80 should not be dogmatically employed as a criterion for profile invalidity; profiles with this *F* scale elevation may actually be valid, especially with a prison population. A high *F* scale score does not seem to necessarily indicate any single behavior or diagnosis but may be associated with a generally nonconforming, hostile, and aggressive approach to life. Although examination of *F* scale item endorsements on individual profiles may provide useful clinical insights, the use of high *F* scale scores in differential diagnosis does not seem to be a promising possibility. Factors such as age and intelligence may also effect *F* scale elevations, but more research using prison populations specifically is needed, especially to check for any interaction effect resembling that found by Gynther and Shimkunas (1965a). Dependable indicators of faked prisoner profiles are sorely needed, but none have been identified to date.

Megargee (Note 3) described a complex approach to the profile validity problem that he and his associates have used in the development of their classification system. Reading levels for prisoners were not determined through any routine testing methods, but those inmates who were found to have reading difficulties were tested orally with a tape-recorded version of the MMPI. The Spanish-speaking inmates were given the Spanish version of the MMPI. After each inmate completed the MMPI, he was required to correctly identify his answers to six test items randomly chosen from his protocol by the examiner. Failure to pass this check necessitated a retest. Profiles with *F* scale *T* scores exceeding 100 were examined clinically for their approximation to the mean random-response clinical-scale pattern, which consists of scores on each scale that are equivalent to the midpoint (i.e., half the items marked in the scorable direction) of that scale. Only those profiles that deviated from this pattern on the validity scales and the clinical scales and that made "clinical sense" were retained as nonrandom.

This approach was the best one encountered by this author, but it still has some drawbacks. For one thing, Megargee states that "obviously some expertise with the MMPI is involved" in the latter clinical scrutinizations of suspect profiles; the validity sections of Dahlstrom et al. (1972) may aid the researcher who lacks such expertise in coming to grips with this challenging interpretive task. Contrary to the previously mentioned IQ/reading-level recommendations, no intelligence testing was done to screen inmates for the MMPI. Again, the testing of subjects lacking the minimal reading-skills criteria has not yet been empirically demonstrated to be a sound methodological practice, and the lack of preliminary reading-level screening cannot be sanctioned. Even so, this approach is more acceptable overall than most being employed today, and the combination of routine screening examinations with Megargee's guidelines is probably the best approach to the issue of MMPI protocol

validity that can be realized presently. One alternative that may prove to be a more economical means for the detection of randomly answered profiles (especially if protocols are being drawn from an accumulated data bank) is the test–retest (TR) index of Buechley and Ball (1952). This index examines the 16 repeated items in the booklet and R forms of the MMPI for consistency of item endorsement and employs a cutoff of more than three disagreements to identify and discard randomly generated profiles. Unfortunately, the lack of dependable fake-bad and fake-good indices cannot be satisfactorily compensated for at this time; the findings of Gendreau et al. (1973) must be cross-validated and built upon to fill this void. Future studies should also investigate the retesting approach for random profiles mentioned above and should consider the use of standardized instructions cautioning against any further attempts at deception. The comparability of such protocols obtained under added duress with protocols obtained in the standard manner would be difficult to assess, however. (See Dahlstrom et al., 1972, pp. 105–106, for a discussion concerning the implications of the forced-choice change in administration; for a more thorough treatment of all of the above validity indicators as well as other validity indicators that have not yet been investigated in the prison population, see the validity sections in Dahlstrom et al., 1972.)

In summary, there is a strong possibility that a good deal of the MMPI research with prisoners has been adversely effected either by the failure to employ any criteria for profile invalidity (causing a confounding of any actual differences between groups by random profiles) or by the overly rigid application of conventional validity criteria (causing a concealment of significant differences between groups by restricting elevation ranges on several scales). The validity criteria used in each study reviewed in the main body of this article will be indicated by a number after the date of each article the first time it is cited (e.g., Beall & Panton, 1956; 1). This number corresponds to the number entered under the V column of Table 2: 1 = no criteria employed; 2 = employed standard cutoffs (*L* scale *T* score maximum of 70, *F* scale *T* score maximum of 80, *K* scale *T* score maximum of 70); 3 = detected and discarded random profiles only. This is intended to aid in the consideration of the possible effects that selection of validity criteria may have had on the findings presented. The present author advocates Alternative 3 as the most appropriate procedure until further research on fake-bad and fake-good indices clarifies their proper application with inmate MMPI profiles.

As mentioned in the introduction, special validity criteria were used in the selection of pre-1967 studies for review. Any such study that either employed standard cutoffs (usually, *L* scale maximum *T* score of 70, *F* scale maximum *T* score of 80, and *K* scale maximum *T* score of 70) or at least provided validity scale data (usually means and standard deviations) were included, since this allows at least a rough assessment of the direction and extent to which the findings may be distorted. Pre-1967 studies that failed to meet these criteria provide no clues for such an assessment and were therefore omitted to keep the present review to a manageable length; the only exceptions made were for studies that generated original experimental scales, for these studies were necessary for purposes of continuity in the review. (See Haven, Note 1, for a more comprehensive review of pre-1967 studies.)

Methods of Profile Interpretation

One crucial choice that any MMPI researcher must make is which of the several ways of viewing MMPI data will maximize the quality and quantity of useful information gained from the protocols. The studies reviewed in this article consider one or more of several protocol aspects, including conventional scale elevations, mean profile configurations for each group, actuarial high-point coding systems, a sequential linear-sums model, and experimental scales using cutoff scores. Costello et al.'s (1972) previously reviewed study on racial differences (see the section on Sources of Variance and Their Effects on Test Results) examined the variations within the significant findings of

several different data assessment approaches that were applied to the same set of MMPI protocols. They found that consideration of isolated scale elevation means between groups produced significance on the *F, K, Hs, Mf, Sc,* and *Ma* scales, whereas a high-point coding approach identified the *Mf, Pa, Sc,* and *Si* scales, and a two-digit coding analysis identified the *Hs, D, Pd, Pa, Pt,* and *Sc* scales. They concluded that "inferences drawn from contrasting differences would depend on the particular dependent measure employed" (p. 167). Black's (1967) study (see the section on Recidivism) serves as a valuable object lesson in this respect; even though initial investigation of isolated scale elevations failed to produce significant differences between his recidivist and nonrecidivist groups, Black carried out further analyses in a highly resourceful manner until he obtained a combination of indices that correctly identified 90% of his overall sample. Efficient maximization of profile data may demand the investigation of several different approaches simultaneously, for the above two studies suggest that not only the nature of interpretation of results but even the efficient detection of existing significant differences are a function of the type of MMPI dependent measure employed.

Gregory's (1974; see the section on Classification of Psychopathologic Behavior) unique sequential linear-sums approach also deserves consideration here. Essentially, this approach used a stepwise regression analysis that employed the conventional MMPI scales as predictor variables and the classifications based on checklist ratings of available case history data as criterion variables. His three index formulas successfully classified 63% of his overall sample as psychopathic, adjusted, or neurotic. Gregory's perspective is that

> the evaluation of code type systems should be pragmatic, that is, based on the proportion of target population profiles that can be interpreted within the system and on the degree to which stable and useful personality correlates are generated . . . *utility* must always have the final say. (p. 391, italics in original)

The extent to which Gregory's approach lives up to this standard as compared with other approaches needs to be examined with further comparison research in the prison population.

In their important and extensive work on the efficiency of predictive psychometric indicators, Meehl and Rosen (1955) identified a critical methodological point, not observed by most of the predictive studies in this review, that used "cutting scores" on experimental scales. Such studies usually isolate those MMPI items that differentiate best between their research groups and use these items to form an experimental scale. The distribution of total scores on the scale is examined for each of the two groups, and the single score that maximizes the differentiation of the two groups (i.e., the first group mostly falls on one side of this score, whereas the second group mostly falls on the opposite side of this score) is designated the "cutting score" for the scale. However, Meehl and Rosen point out the necessity of considering the base rate of occurrence of a given criterion variable in the overall population under study in the investigations of this type. This is required because a psychometric predictor such as an experimental MMPI scale that at first blush appears to make an impressive differentiation may actually cause more incorrect identifications than the base-rate differentiation. This is particularly a problem when the criterion variable normally occurs in almost all or almost none of the population under study, whereas it ceases to be a problem when the criterion variable normally occurs in approximately 50% of this population.

Shupe and Bramwell (1963; this study did not meet the validity criteria and is not included in the Review section) constitute an example of this problem in their investigation of the Prison Escape (*Ec*) scale. Since the base rate of escape at their institution was about 5%, their sample results indicated that the *Ec* scale could predict escape risk in the overall population with 90% accuracy. However, Shupe and Bramwell realized that even though they could correctly predict escape risk in all prisoners 90% of the time by using the *Ec* scale, they would correctly predict escape risk in all prisoners 95% of the time if they predicted

that no inmates would escape. Another problem with the *Ec* scale is that it would produce about 7.6% false positives (nonescapees incorrectly labeled as escapees) in the overall population, whereas base-rate prediction would produce no false positives, since it predicts that no one will escape. These findings are a powerful illustration of Meehl and Rosen's disquieting assertion that "*deciding on the basis of more information can actually worsen the chances of a correct decision*" (p. 202, italics theirs). In view of this methodological revelation, Gough, Wenk, and Rozynko's (1965; see the section on Recidivism) prescription seems most appropriate:

> All claims as to predictive accuracy must be stringently verified by utility analyses. In essence, this means that in any prediction a chance level of accuracy must be defined, based on the observed frequency of the criterion, and then the diagnostic or forecasting technique must be contrasted with this chance level. (p. 433)

Any researcher involved in predicting anything from MMPI inmate profiles should incorporate this crucial point and Meehl and Rosen's other methodological requirements and helpful suggestions into their experimental design (see also Cronbach & Gleser, 1965). Unfortunately, Gough et al.'s study is the only work of a predictive nature reviewed in this article that followed Meehl and Rosen's recommendations. The other predictive researchers reviewed here should obtain appropriate base-rate figures from their overall sample population and reevaluate their findings following Meehl and Rosen's prescriptions. The true utility of their findings could not be assessed adequately in every case in this article, since few studies provided the appropriate base-rate figures. Although Meehl and Rosen point out that certain special situations (e.g., see the discussion on suicide in the section on Institutional Adjustment) mitigate the relevant applicability of chance level prediction accuracy, their guidelines should be considered nonetheless; the pros and cons of using base-rate prediction in any situation must be individually assessed for the particular situation in question.

Table 3
Experimental Scales Among the Significant Results of the Studies Reviewed

Symbol	Scale
A	Anxiety
AI	Anxiety Index
Al	Alcoholism
Ap	Prison Adjustment
As	Asocial
Asx	Aggravated Sex
At	Anxiety
CI	Critical Item
CR	Conversion Reaction
DaS	Drug Abuser
Dc&i	Defect of Inhibition Control
DH	Direction of Hostility
Dn	Denial
Ec	Prison Escape
Em	Emotional Immaturity
Eo	Ego Overcontrol
ES	Ego Strength
Ex	Extraversion
FTI	Frustration Tolerance Index
GH	General Hostility
HC	Habitual Criminal
He	Heroin
Hsx	Homosexual
Hy2	Need for Affection and Reinforcement subscale
Hy3	Lassitude-Malaise subscale
In	Inner Maladjustment
Jh	Judged Manifest Hostility
Ma1	Amorality subscale
Ma2	Psychomotor Acceleration subscale
Ma3	Imperturbability subscale
Ma4	Ego Inflation subscale
Mf1	Personal and Emotional Sensitivity subscale
Mf5	Denial of Masculine Occupations subscale
Mp	Positive Malingering
O-H	Overcontrolled Hostility
Pa1	Ideas of External Influence subscale
Pa2	Poignancy subscale
PAS	Prison Adjustment
PaV	Parole Violator
Pd1	Family Discord subscale
Pd2	Authority Conflict subscale
Pd4A	Social Alienation subscale
PM	Prison Maladjustment
Pq	Psychotic Tendency
Pr	Prejudice
R	Repression
Re	Responsibility
Rmn	Recidivism-Rehabilitation
R-S	Repression-Sensitization
Sc1A	Social Alienation subscale
Sc2A	Lack of Ego Mastery-Cognitive subscale
SD	Sensorimotor Dissociation

Table 3 lists all of the abbreviations and corresponding names of the experimental scales and the conventional clinical scale subscales that were among the significant findings of the studies reviewed.

(See Butcher & Tellegen, 1978, for additional recommendations concerning the methodological design of MMPI research in general.)

Review

The preceding methodological evaluation revealed several methodological shortcomings within the designs of the studies to be reviewed. As a result, the interpretation and generalization of the present findings are restricted. These studies can best be viewed as indicative of the potential general usefulness of the MMPI in many different areas of prison work rather than a final judgment of its value to corrections. The findings below will perhaps serve as starting points for better controlled studies, which should attempt to cross-validate and extend these results.

The present section reviews the studies in the following three main categories: The MMPI As a Primary Differentiator of Deviant Behavior, the MMPI As a Predictor of Deviant Behavior, and MMPI Differences Across Race and Sex. The first category is broken down into five sections: hostile-assaultive, first offenders versus recidivists, sexual deviancy, addictions, and classification of psychopathologic behavior. The second category is broken down into three sections: recidivism, prison escape, and institutional adjustment. Finally, the third category is broken down into two sections: racial differences and sex differences.

The MMPI As a Primary Differentiator of Deviant Behavior

Hostile-assaultive. The most extensive work in this field has centered around the development and validation of the Overcontrolled Hostility (*O-H*) scale by Megargee and his associates. Initially Megargee and Mendelsohn (1962; 2) attempted to differentiate between assaultive and nonassaultive criminals using 12 relevant experimental scales. No scale correctly isolated the assaultive group in the predicted manner, but the authors noticed one surprising trend: The protocols of the nonviolent group made them appear less controlled or more hostile than the aggressive groups. They suggested the following hypothesis:

> The extremely assaultive person is often a fairly mild-mannered, long-suffering individual who buries his resentment under rigid and brittle controls. Under certain circumstances he may lash out and release all his aggression in one, often disastrous, act. Afterwards he reverts to his usual overcontrolled defenses. Thus he may be more of a menace than the verbally aggressive, "chip-on-the-shoulder," type who releases his aggression in small doses. (p. 437)

Megargee, Cook, and Mendelsohn (1967; 2) explored this hypothesis in a complex study consisting of the generation of the 31-item *O-H* scale and two cross-validation attempts. They found that the scale seemed to identify the co-occurrence of two usually incompatible personality constructs, impulse control and hostile alienation. They felt that a high *O-H* scale score indicated "a conflict between strong aggressive impulses and strong inhibitions against the expression of aggression" (p. 528), which can manifest itself either in explosive violent acts or psychosis. They concluded that although the generation of an all-purpose assaultiveness scale from the MMPI seems unlikely, the *O-H* scale is capable of identifying a subgroup of assaultive criminals who are of this overcontrolled type. Megargee et al. (1967) did not advocate a specific cutting score. The best cutting score for their data identified 85.7% of the "extremely assaultive" type, producing 43.2% false positives.

Deiker (1974; 1) examined the *O-H* scale along with the conventional scales and 20 other experimental aggression scales on the MMPIs of four experimental groups: homicide, battery, threat, and a control group. Differences on 17 of the experimental scales were significant, but only 4 scales showed significance in the predicted direction: *O-H*, Ego Overcontrol (*Eo*), Direction of Hostility (*DH*), and Denial (*Dn*). Significant differences were also observed on the *F*, *K*, *Pd*, *Pt*, *Sc*, and *Ma* scales, with the control

group having the highest elevations on all except the *K* scale. Deiker concluded that although his results seemed to support Megargee (1966), a negative response bias hypothesis accounted for the results equally well. (The *O-H* scale has 21 items keyed false and 10 items keyed true.) Megargee and Cook (1975; 2) responded to this criticism by constructing two shortened and two lengthened *O-H* scales, all with equal numbers of scorable true and false items. They reanalyzed their initial set of protocols and found that one of the lengthened scales was actually a better discriminator than the original *O-H* scale, thereby refuting the negative-response bias hypothesis. Neither of these studies used cutting scores, instead they compared group means.

Davis and Sines (1971; 1) have discovered a profile configuration that seems to be associated with hostile-aggressive acting-out behavior. (These 4-3 studies are the sole exceptions to the prototypical research design included in this review, since their approach resembles that of Megargee et al., 1967. However, the importance and relevance of these findings demanded their inclusion in this review.) They concisely defined the 4-3 configurational prototype (profile peak on the *Pd* scale with the second highest elevation on the *Hy* scale) and examined the differences between these profiles and a control group's profiles in each of three settings: a state hospital, a prison, and a medical center. A behavioral pattern of hostile-aggressive outbursts in usually quiet men consistently emerged across the three settings. The authors pointed out that this behavioral pattern is similar to Megargee's *O-H* type and Gilberstadt and Duker's (cited in Davis and Sines, 1971) "4-type," and they concluded that the consistency of their findings both across their samples and with previous work constitutes strong evidence of the prototype's validity. They speculated that 4-3 profile types have a constitutional predisposition toward this behavior pattern: 4-3 types seem to be controlled by a cyclical internal mechanism that periodically causes acute emotional and behavioral disturbances and seems impervious to conventional treatment methods. Persons and Marks (1971; 1) successfully replicated these results, noting the significantly higher incidence of violent crimes by 4-3 types when compared to three of the most common MMPI code types in prison. Davis (1971; 1) also obtained similar results with a female inmate population. The nature of these studies precluded the determining of false-positive rates.

Two other studies were found that investigated aggression in prisoners. Blackburn (1968; 1) found that his "extremely assaultive" group scored significantly higher than his "moderately assaultive" group on the *L, K, R, Eo,* and *Dn* scales and significantly lower on the *F, Pd, Ma,* Extraversion (*Ex*), and General Hostility (*GH*) scales. Even though the *O-H* scale was not yet available to him for this study, Blackburn concluded that his findings supported Megargee's (Megargee, 1966) overcontrolled hostility hypothesis. Carroll and Fuller (1971; 1) compared nonviolent, violent, and sexual offenders and found that the nonviolent group appeared to be hostile and confused in thinking and displayed the most deviant profiles. These nonviolent subjects were found to be significantly higher than the other two groups on the *F, Sc,* and *Ma* scales. Their findings would also seem to support Megargee's hypothesis; it is unfortunate that the *O-H* scale was not included in their analysis.

The potential value of these important findings is self-evident. The identification of potentially violent inmates with the help of the MMPI would aid in treatment plans, administrative decisions, and parole considerations. As Megargee and Mendelsohn (1962) point out, the detection of assaultiveness of the overcontrolled variety can be a difficult task, since these types usually appear so passive and mild-mannered. The cyclical nature of the 4-3 prototype may also be initially deceptive. Even though not all violent criminals are identified by these two major indices, these indices seem to isolate those types who may not be seen as assaultive until a harmful outburst occurs. Although further cross-validation is needed, the already demonstrated discriminative powers of both the *O-H* scale and the 4-3 prototype are encouraging. However, investigation of false-positive rates for both in-

dices must be pursued. Comparisons of high *O-H* scale profiles and 4-3 profiles should be carried out to determine if they are measuring essentially the same thing.

First offenders versus recidivists. A few studies have attempted to differentiate first offenders from recidivists with MMPIs obtained after the recidivists had returned to prison. Dunham (1954; 1) found that the *D* and *Pd* scales were significantly higher for recidivists, whereas Stanton (1956; 2) found that the *Pd* and *Ma* scales were higher. Panton (1959a; 2) found no significant differences between first offenders and recidivists. Others who have not restricted themselves to the conventional MMPI scales have come up with somewhat more meaningful results. Panton (1962b; 1) found that recidivists were significantly higher on the *Pd, Ma,* and Prison Adjustment (*Ap*) scales and combined the *Pd* and *Ap* scales to form the new Habitual Criminal (*HC*) scale. However, the results of his cross-validation (which blocked on age and number of prior offenses) were not compelling, and he noted that the scale seemed to get less effective as the number of prior offenses decreased. Pierce's (1972a; 1) attempt at cross-validation of the *HC* scale succeeded in effectively differentiating first offenders from recidivists. (He did not select a cutoff score, however.) Adams (1976; 2) also reexamined the *HC* scale and found that it effectively differentiated recidivists from first offenders, as did its parent scales *Pd* and *Ap*. Flanagan and Lewis (1974; 2) found that offenders with juvenile records scored significantly higher than "absolute first offenders" on the *F, Pd, Pa, Sc,* and *Ma* scales and significantly lower on the Responsibility (*Re*) scale. Christensen and LeUnes (1974; 1) used the Prison Adjustment Scale (*PAS*) in addition to the conventional scales, but they failed to achieve any significant differentiations with respect to recidivism.

These results are of little direct predictive usefulness due to their post hoc nature. Observed differences within this paradigm cannot be equated with differences extant in future recidivists before their initial release from prison. The most consistently significant findings across these studies showed recidivists to have relatively higher evaluations on the *Pd* and *Ma* scales, but these are common peaks for prison populations that are frequently above a *T* score of 70. Therefore, these results seem to offer no dynamic insights that could be useful in treatment approaches. The only possible utility the *HC* scale might have is if it could predict recidivism before the fact. In short, little useful information seems to be contained in these studies. (More directly predictive studies are examined in the section on Recidivism.)

Sexual deviancy. Work in this area has centered around the identification of homosexuals. Panton (1960b; 2) found the conventional *Mf* scale to be ineffective for this purpose, so he generated the Homosexual (*Hsx*) experimental scale. This scale identified 81% of the homosexuals and 87% of the nonhomosexuals in his initial sample and 86% of the homosexuals and 81% of the nonhomosexuals in his cross-validation sample. Pierce (1972b; 1) found that the *Hsx* scale identified 94% of his "active homosexual" group, 100% of his "situational homosexual" group (heterosexual before coming to prison), and 100% of his comparison group. A second study by Pierce (1973; 1) that used the *Hsx* scale differentiated 81% of his active homosexual group and 81% of his situational homosexual group with a cutoff score of 9.8, and scores on the scale remained relatively stable on a retest 1 year later. Another study by Pierce (Note 4; 1) that used both the *Hsx* scale and the *Mf* scale found that mean scale score differences for both scales successfully differentiated his active homosexual group from his situational homosexual and nonhomosexual groups, whereas neither scale successfully differentiated the latter two groups from each other. However, Cubitt and Gendreau (1972; 1) failed to effectively differentiate their homosexual group with the *Hsx* scale, even though other scales did significantly differentiate (i.e., the *Hs, D, Hy, Mf, Pa,* and both of Manosevitz's abridged *Mf* scales [Manosevitz, 1970]). They noted that their homosexual group was significantly older and that *Hsx* scores demonstrated a significant positive correlation with age; this should have exaggerated the power of the

Hsx scale to detect homosexuals in their sample. Cubitt and Gendreau conclude that the validity of the *Hsx* scale is "limited" but that the *Mf* scale (and Manosevitz's abridged versions) effectively discriminates homosexuals from heterosexuals. Panton's (1978; 1) most recent study effectively discriminated prior-to-incarceration homosexuals from a baseline prison sample, finding that homosexuals scored significantly higher on the *Mf, Pa, Sc, Ma, Hsx,* and Frustration Tolerance Index (*FTI*; Beall & Panton, Note 5) scales. These results led Panton to conclude that homosexuals exhibit "an implied greater social alienation and weaker impulse control characterized by a more likely acting-out to stress and frustration than is indicated for the population sample as a whole" (p. 11). Panton also found significant differences among demographic variables and Sex Inventory (Thorne, 1966) scales. He offered the overall conclusion that the homosexual entering prison will probably pursue his homosexual inclinations but will not necessarily become sexually assaultive in these pursuits.

Two other studies were found that examined group differences on conventional MMPI scales. Oliver and Mosher (1968; 1) compared a group of heterosexuals with homosexual "inserters" and homosexual "insertees." There were no significant differences between the two homosexual groups (possibly due to a small *N*), but the insertees were significantly higher than the heterosexuals on the *Hs, Hy, Pd, Mf,* and *Pt* scales, whereas the inserters were significantly higher on the *F, Hs, D, Hy, Pd, Pa, Pt,* and *Sc* scales. McCreary (1975; 1) compared child molesters with previous offenses to first-offense child molesters and found that previous offenders scored significantly higher on the *Pd, Pd2, Hs, Hy,* and *Sc* scales.

Although the MMPI appears to be sensitive to differences between homosexuals and heterosexuals, no one specific indicator was consistently effective across all studies. Cubitt and Gendreau's (1972) study was conducted in a Canadian prison, and as a result cultural differences may partially explain the failure of the *Hsx* scale to differentiate in their sample. Manosevitz's abridged *Mf* scales need to be examined further with prison populations. A number of the previously mentioned studies (Oliver & Mosher, 1968; Panton, 1978; Pierce, 1972) discuss the several types of disciplinary problems centering around the homosexual inmate (including fighting, homosexual seduction and rape, and attempted suicides or escapes to avoid homosexual demands), which dramatize the need to identify types of homosexual inmates as soon as possible for effective and beneficial treatment approaches and administrative decisions. Due to a lack of truly accurate figures for the incidence of inmate homosexuality as well as the possible human expense resulting from false negatives in chance prediction, Meehl and Rosen's (1955) base-rate prescriptions seem to be inapplicable here. All of the above research was conducted after homosexual behavior had already been detected in the criterion groups, which seems to be a sensible approach considering the relative stability of homosexual behavior over time. However, more research of a longitudinal nature is needed, preferably combining MMPI protocols obtained on admission with careful follow-up procedures to maximize the predictive utility of the MMPI in coping with problems caused by inmate homosexuality. Distinctions between types of homosexuals such as those made by Oliver and Mosher could prove to be valuable in assisting future predictive studies to identify homosexual subtypes who may instigate some of the disciplinary problems previously mentioned. Other types of sexual deviancy (such as sexual offenders) have yet to be explored to any significant extent, but the MMPI may also prove to be useful in these areas.

Addictions. A few studies have examined drug addiction by limiting themselves to the conventional MMPI scales. Gendreau and Gendreau (1970; 1) failed to find any significant differences between their groups of heroin addicts and nonaddicts and concluded that the "addiction-prone" theory (which seeks to ascribe specific personality traits to addicts) is an inappropriate approach to the problem. Panton (1977; 2) compared drug dealers to drug abusers and found that dealers scored significantly higher on the *Ma,* Amorality (*Ma1*), Psychomotor Acceleration

(*Ma2*), and Ego Inflation (*Ma4*) scales and significantly lower on the *Hs, D, Hy, Pt,* and *Si* scales. He concluded that drug dealers are a more difficult management and treatment problem than drug abusers.

Cavior, Kurtzberg, and Lipton (1967; 1) compared heroin addicts to nonaddicts and generated the Heroin (*He*) experimental scale that when applied to two cross-validation samples, correctly classified 75% of the overall adult sample and 67% of the overall adolescent sample. As part of a larger study, Panton and Brisson (1971; 2) compared drug abusers with nonusers and found that the drug group scored significantly lower on the Aggravated Sex (*Asx*) scale, significantly higher on the *Hy, Pd, Mf, Sc, Ma, Pa, Ec,* and *HC* scales and significantly higher on the Need for Affection (*Hy2*), Lassitude-Malaise (*Hy3*), Familial Discord (*Pd1*), Authority Problems (*Pd2*), Social Alienation (*Pd4A*), Personal and Emotional Sensitivity (*Mf1*), Denial of Masculine Occupations (*Mf5*), Social Alienation (*Sc1A*), Lack of Ego Mastery-Cognitive (*Sc2A*), and Imperturbability (*Ma3*) subscales. These results tended to support the several findings they had made through their examination of their other sources of data. Panton and Brisson also generated the Drug Abuser (*DaS*) experimental scale, which identified 75.4% of the drug abusers and 81.4% of the nonusers in their initial sample and 75.8% of both groups in a cross-validation sample. Panton and Behre (1973; 1) compared drug addicts to abusers without addiction on the conventional MMPI scales, 11 experimental scales (not including *He* or *DaS*) and several demographic variables. Contrary to Panton and Brisson's findings, they found no significant differences on the MMPI (several demographic variables did differentiate, however). The authors concluded that

> the MMPI results . . . support the contention of Gendreau and Gendreau that there is no such diagnostic identity as the addition-prone personality, and that imprisoned narcotics addicts do not necessarily have unique personality traits, as measured by the MMPI which predispose them toward the special effects of heroin, or distinguish them from non-addicted imprisoned drug abusers. (p. 416)

Panton (1972; 1) also investigated the validity of three alcoholism scales in a prison population. In comparing a prison alcoholic group with a prison nonalcoholic group and a normal nonalcoholic group, he found that the Alcoholism (*Al*) scale successfully differentiated the prison alcoholics (65.8% hit rate) from the prison nonalcoholics (also 65.8% hit rate). The second Alcoholism (*Am*) scale only differentiated the normal group from the prison groups, and the third Alcoholism (*Ah*) scale failed to achieve any differentiation. Panton concluded that even the *Al* scale seems to be affected by a more general factor of sociopathy, however. As part of his larger study, Stanton (1956; see the section on First Offenders Versus Recidivists) compared alcoholics with narcotics addicts and nonaddicts and found that alcoholics scored significantly higher on the *Pd* scale than either addicts or nonaddicts. He found no differences between the addict and nonaddict groups.

These sparse results are difficult to compare, since the criteria for formation of the criterion groups vary widely across the studies. Furthermore, little practically useful predictive potential is apparent, and the addiction-prone personality theory has not received any support. More reliable and expedient means of identifying addicts are already at the disposal of correctional personnel, so the application of experimental MMPI scales seems unnecessary. The MMPI might be able to identify prognostically favorable signs that could aid in the treatment of addicts, but evidence of such indicators does not presently exist. In short, the MMPI has not been shown to offer any practically significant insights into the addiction problem that cannot be more reliably gained from other sources; a productive use of the MMPI in this area has yet to be demonstrated.

Classification of psychopathologic behavior. Some studies have investigated the extent to which the MMPI can differentiate between different types of psychopathologic behavior. Gynther (1962; 1) examined the performance of 12 crime category groups of court-referred patients on the *F* scale and concluded that larger *F* values indicate "sicker" subjects. Craddick (1962; 1) extracted a

group of psychopaths and a group of nonpsychopaths from a larger pool of prisoners on the basis of scores on a checklist of psychopathic characteristics that he filled out for each prisoner. He found that the psychopaths obtained significantly higher scores on the *Pd, Pt,* and *Ma* scales. Johnston and Cooke (1973; 1) separated one pool of prisoners into four pairs of mutually overlapping groups (aggressive vs. nonaggressive, maximum security vs. nonsecurity placement, escape precaution vs. no precaution, and alcoholic diagnosis vs. nonalcoholic diagnosis) on the basis of behavioral records and clinical judgments. They found no significant differences between any of these pairs on the *Ah, Ec, Hc,* or Recidivism (*Rc*) experimental scales.

Several studies have used and expanded on theoretical classifications like Lindesmith and Dunham's (cited in Randolph, Richardson, & Johnson, 1961) socialized versus individualized juvenile delinquent types. Randolph et al. (1961; 2) paraphrased Lindesmith and Dunham's descriptions of these types as follows: "The socialized criminal is one who commits crimes that are supported and prescribed by his culture, so that, by committing a crime, the criminal gains in status and recognition" (p. 293). On the other hand, "the individualized criminal . . . acts for reasons that are personal and private. He commits his crimes alone and, in theory, is a stranger to others who commit similar crimes" (p. 293). Furthermore, "the socialized criminal seems likely to be a rather normal person," whereas "the individualized criminal, at odds with his own primary group, seems likely to be an individual whose criminality is merely symptomatic of deeper psychological pressures" (p. 293). Randolph et al. compared groups of these two types on the conventional scales and found that although profile configurations were similar, the solitary delinquents scored significantly higher on all clinical scales except the *Ma* scale. Wilcock (1964; 1) added an aggressive socialized group to his samples approximating the above two groups (this new group was described as combining certain elements of the first two groups) but merely found that the individualized group scored significantly higher than the other two groups on the *Hs* and *Hy* scales. (A small *N* may partially account for this lack of significance.)

Shinohara and Jenkins (1967; 3) used Jenkins' classifications (the first two of which are highly similar to Lindesmith and Dunham's two basic types) of socialized versus unsocialized aggressive versus runaway delinquents. This latter type was characterized "by repeatedly running away from home overnight, by staying out late at night, by stealing *in the home* . . . and by stealing which is furtive rather than aggressive" (Shinohara & Jenkins, 1967, p. 157; italics theirs). They examined differences between these groups on the conventional scales and 8 experimental scales. They found that the unsocialized aggressive group scored significantly higher than the socialized group on the *F, Hs, D, Pd, Pa, Sc,* and Anxiety (*At*) scales, whereas the runaway group scored significantly higher than the socialized group on the *F, Hs, D, Hy, Pd, Mf, Pt, Sc, At,* and Asocial (*As*) scales. They also found that the runaway group scored significantly higher than the unsocialized aggressive group on the *Mf* scale but scored significantly lower on the *Pa* scale. They concluded that the socialized group showed much less psychopathology and that their delinquency was "typically adaptive goal-oriented motivation behavior," whereas the other two groups showed more psychopathology and their delinquency was "frustration behavior rather than adaptive behavior" (pp. 161–162). Tsubouchi and Jenkins (1969; 3) attempted to validate and extend these findings using the conventional scales and 10 experimental scales. They found that their unsocialized aggressive group scored significantly higher than the socialized group on the *F, Hs, D, Pd, Pt,* Emotional Maturity (*Em*), and *HC* scales, whereas the runaway group scored significantly higher than the socialized group on the *F, Pd, Sc, Pa,* and *Em* scales. They also found that the unsocialized aggressive group scored significantly higher than the runaway group on the *Hs* scale. They concluded that the findings of Shinohara and Jenkins were essentially supported. In addition, they generated an experimental scale (unnamed) that separated their "motiva-

tion" delinquents (the socialized group) from their "frustration" delinquents (the other two groups).

Gregory (1974; 1) took a unique approach to this problem by generating sequential linear-sums formulas to identify delinquents who had been classified as psychopathic, adjusted, or neurotic on the basis of clinical graduate student checklist ratings of commitment summaries. Of Gregory's overall sample, 63% was classifiable by these three formulas, which used T scores on standard scales (e.g., Psychopathic Index [PI] $= F + 2Pd + Ma - 2K - Pt - 2Si - 40$). Gregory suggested that this approach to classification may be more efficient in general than the three other approaches to profile typing that he inspected and discarded as inadequate. (The three types are clinically derived code types, two-point techniques, and the "D^2 method.") Although Gregory emphasized the need for replication, no other studies were found that addressed his findings.

The work based on theoretical classifications such as Lindesmith and Dunham's (cited in Randolph et al., 1961) seems to be the most promising approach in this area at this point. Although criteria for inclusion into the different criterion groups varied across the studies, three out of four studies found extensive significant differences that supported their theoretical hypotheses. The pursuit of these findings could be profitable in maximizing the effectiveness of differential treatment approaches to these various groupings. More stable prima facie indicators derived from the MMPI for these criminal types would be a desirable extension of these findings; the investigation of Tsubouchi and Jenkins' (1969) experimental scale and the generation of other experimental scales toward this end seems to be the most advisable approach. The possible presence of prognostic MMPI indicators for these groups should also be examined. Gregory's sequential linear-sums approach demands further investigation, both with respect to his specific findings and to the general utility of his linear-sums methodology. The work of Megargee (1977) and his associates appears to be a more extensive and comprehensive effort at this type of classificatory MMPI system, but perhaps Megargee's empirical approach could be productively interfaced with the theoretical and empirical approaches previously described.

The MMPI As a Predictor of Deviant Behavior

Recidivism. These studies are distinguished from those in the First Offenders Versus Recidivists section in that they compare the MMPIs of recidivists and nonrecidivists that were administered before each subject's initial release from prison. Instead of a post hoc analysis seeking possible treatment approaches, these studies concentrate on using the MMPI as a reliable predictor of future recidivists. The base-rate predictive guidelines of Meehl and Rosen (1955) are particularly relevant here. Frank (1971; discussed later) cites the following Task Force on Corrections (1967) findings: "The best current estimates indicate that, among adult offenders, 35 to 45 per cent of those released on parole are subsequently returned to prison" (p. 3). Therefore, any study in this area that attempts to claim any practical significant value must comfortably exceed the 65% overall hit rate that could be realized by merely predicting that no released inmate will return to prison. The rate of false positives (those identified by the MMPI as recidivists who are actually nonrecidivists) must also be weighed against any gains over this chance expectancy figure (which creates false negatives only).

Only one study was found that confined itself to the examination of conventional MMPI scales. Mack (1969; 3) found no significant differences between his group of recidivists and parole successes. Other studies have attempted to generate or employ experimental scales as predictive indicators of recidivism. As part of a larger study, Gough et al. (1965; 1) examined the conventional scales and the Anxiety (A), Repression (R), and Ego Strength (ES) scales, and found that only the Ma scale was significantly higher for recidivists. Panton (1962c; 2) generated the 26-item Parole Violator (PaV) scale that identified 80.5% of the violators

and 80.5% of the nonviolators in his initial sample (an overall hit rate of 80.5%, with 12.7% false positives) and 78.6% of a cross-validation sample consisting solely of violators. He also found that nonviolators scored significantly lower than violators on the *Hs*, *D*, *Hy*, *Pd*, *Pa*, *Pt*, *Sc*, and *Ma* scales and significantly higher on the *Mf* scale.

A major work in this area is the dissertation of Black (1967; 2). He examined 15 experimental scales as well as the conventional scales and found that no single scale achieved a significant differentiation between his groups of recidivists and nonrecidivists. However, he took two of the scales (*Si* and *HC*) that had the highest correlations with the criterion, selected items that the two groups had responded to differentially five or more times, eliminated overlapping items, and called the results the Recidivism–Rehabilitation scale (*Rmn*; inspection reveals that this scale does not share any items with Panton's *PaV* scale). This 22-item scale initially identified 88% of the recidivists and 84% of the nonrecidivists in his sample. Attempting to improve on these results, Black then constructed the *Rmn* index, which yields a score of 1 point for each of the following scale elevation criteria: *Si* scale *T* score less than 54, *HC* scale *T* score greater than 58, *Rmn* scale *T* score greater than 50. Scores of 0 and 1 on this index were found to predict rehabilitation, and a score of 3 was found to predict recidivism, with a score of 2 being indecisive. However, Black found that the arithmetical difference between the *A* and *R* experimental scales successfully identified 80% of the two-score recidivists with differences of 8 or less and 75% of the two-score nonrecidivists with differences greater than 8. This combined system achieved an overall predictive accuracy of 90%, with only a 7.8% rate of false positives. Black organized all of his findings into the Recidivism–Rehabilitation Inventory, which presents the following scales in a format modeled after the conventional MMPI profile sheet: *L*, *F*, *K*, *Si*, *HC*, *Rmn*, *A*, *R*, *PaV*, *Pd*, *Ma*, *Ec*, and *ES*.

A dissertation by Frank (1971; 2) sought to cross-validate these findings. He found that the *Rmn* scale alone was the best predictor for his sample, identifying 75.5% of the parole successes and 68% of the recidivists (a 73.1% overall hit rate, with 15.9% false positives). The *Rmn* index identified 80.0% of the successes and 54.4% of the recidivists (an overall hit rate of 71.0% with 13% false positives), and Frank found that the major cause of misclassifications seemed to be the *A* scale minus *R* scale difference for *Rmn* index scorers of two. Frank points out that Black's subjects were tested just prior to release, whereas his subjects were tested on their initial admission to prison, and he admits that the failure of his testing procedure to include the effects of incarceration may have compromised the predictive powers of the *Rmn* scale and index. He found that no single item of the *Rmn* scale was a more efficient discriminator than the scale as a whole, and this led him to tentatively conclude that "the Recidivism–Rehabilitation scale taps a recidivist 'syndrome,' a personality dimension with overt MMPI response tendencies" (pp. 37, 39).

Two studies reviewed elsewhere in this article make passing reference to the prediction of recidivism. Wattron (1963; see the section on Institutional Adjustment) found that his 72-item Prison Maladjustment Scale (*PM*) identified 68% of his recidivists and 69% of his successful parolee group (an overall hit rate of 68.7%, with 20.1% false positives. Inspection reveals only a four-item overlap between the *PM* and *Rmn* scales: Items 56, 118, 216, and 469 all scored true). Davis and Sines (1971; see the Hostile-Assaultive section) noted that the 12 men in their sample with 4–3 profiles who were subsequently paroled all violated parole within 1 year of release.

The only study that showed an appreciable gain over chance prediction in percentage of overall hit rate with a corresponding smaller percentage of false positives was Black's (1967) work on the *Rmn* scale and index. The potential value of these findings cannot be assessed at this time, but they demand attempts at cross-validation, since even the shrinkage in accuracy that is expected would still allow a significant improvement over chance prediction. Black's work also includes an extensive review of the

literature on recidivism, and he effectively integrates his findings with the theories and research findings of others in the field. The implications for both the successful identification of future recidivists and the formulation of more effective treatment approaches for this particular group are far-reaching indeed. Frank's (1971) attempted cross-validation of Black's findings was disappointing, but it was compromised by the difference from Black's procedure in the timing of MMPI administration; it seems reasonable to assume that MMPIs administered just prior to release would probably be better discriminators of recidivism than MMPIs given on initial admission to prison. (In fact, Table 2 reveals that Black's study was the only study reviewed that administered all MMPIs just prior to release.) Also, success by Frank would not have greatly extended the generalizability of the *Rmn* scale and index anyway because he conducted his replication in the same state as Black's original work (Oklahoma). Further cross-validations that replicate Black's methodology more precisely must be conducted in other parts of the country before the value of Black's findings can be adequately assessed.

Panton's *PaV* scale showed some gain in percentage of accurate prediction while producing a corresponding smaller percentage of false positives; future studies may also profit by considering the *PaV* scale along with Black's *Rmn* scale and index. Attempts at cross-validation must incorporate the vital requirement of adequate follow-up to minimize contamination of their nonrecidivist sample with "recidivists-to-be." Frank cites evidence that indicates that over 80% of recidivists return to prison within 2 years of release, so it would seem that a thorough 2-year follow-up would be a minimum requirement for such studies. In summary, it would seem that the predictive powers of the MMPI for the identification and treatment of potential recidivism with the use of the *Rmn* scale and index appear to be promising but need further study.

Prison escape. Once again, Meehl and Rosen's (1955) criteria constitute the focal point of this evaluation. Shupe and Bramwell's (1963; see the section on Methods of Profile Interpretation) 5% escape figure will be used to estimate the effectiveness of predicting escape risk, since the studies discussed in this section did not supply escape base rates for their particular prison populations. Therefore, a successful escape predictor should exceed a 95% overall hit rate with a minuscule incidence of false positives. This is a tall order indeed.

All work in this area has centered around the 42-item *Ec* scale that was generated by Beall and Panton (1956; 1) from a sample tested after escape attempts had already occurred. This scale identified 76.7% of the escapees and 73% of the nonescapees (an overall hit rate of 73.2%, with 25.6% false positives) in the original sample and 77.2% of the escapees and 78.3% of the nonescapees (an overall hit rate of 78.2%, with 20.6% false positives) in the cross-validation sample. Pierce (1971b; 1) employed alternative cutoff scores for two pairs of groups, the first pair with a criterion group having a record of escape prior to the MMPI administration and the second pair with a criterion group having attempted escape subsequent to MMPI administration. Using the cutoffs that achieved the greatest dichotomy, the *Ec* scale identified 80% of the prior escapees and 82% of the nonescapees (an overall hit rate of 81.9%, with 17.1% false positives) in the first pair, whereas in the second pair the *Ec* scale identified 50% of the future escapees and 76% of the nonescapees (an overall hit rate of 74.7%, with 22.8% false positives).

As part of a larger study, Stump and Gilbert (1972; 1) obtained mean scores on the *Ec* scale for a group attempting escape prior to the MMPI and a group attempting escape subsequent to the MMPI and compared these means to the mean *Ec* scale score obtained by the general prison population. The group attempting escape prior to the MMPI had an *Ec* scale mean that was significantly higher than the general population mean, but the other criterion group was not significantly different. Adams and West (1976; 2) found no significant differences between group *Ec* scale means for either of their two comparisons, one in-

volving inmates with one escape attempt subsequent to the MMPI versus a no-escape group and the other involving inmates with two or more escape attempts subsequent to the MMPI versus a no-escape group. Panton (Note 6; 1; Note 7; 2) ran two comparisons with admissions MMPIs, one involving escapees versus nonescapees and the other involving groups with three or more escapes, two escapes, one escape, and no escapes. In the first comparison, the *Ec* scale identified 74% of the escapees and 70% of the nonescapees (an overall hit rate of 70.2%, with 28.5% false positives), whereas in the second comparison the scale identified 90.4% of the three-or-more-escapes group, 86.7% of the two-escapes group, 80.3% of the one-escape group, and 71.4% of the no-escape group (an overall hit rate of 72%, with 27.2% false positives).

Even if the corresponding base escape rate was much higher than the 5% rate assumed here, the *Ec* scale would not appreciably improve prediction over chance expectancy. Unless a high rate of false positives is acceptable for security grade assignment, no benefit is apparent from the scale. Meehl and Rosen (1955) suggest that if a subpopulation can be isolated that has an appreciably higher base rate of the criterion than the overall population in question, indices that lack utility in this overall population may prove to be useful. The classifications of Megargee (1977) and his associates might help in this respect. Perhaps examining the number of escape attempts would be more appropriate than examining the number of actual escapes; this would enlarge the base rate and possibly make the *Ec* scale a more useful tool. However, the *Ec* scale does not seem to have any practical utility at the present time.

Institutional adjustment. Several studies have examined groups of disciplinary problem inmates by focusing primarily on the conventional MMPI scales. Driscoll (1952; 1) created four groups of prisoners ranging on a continuum from "most maladjusted" to "most adjusted." He found that the most adjusted group was significantly higher than any of the other groups on the *D, Mf,* and *Pa* scales and that the most maladjusted group presented the most normal MMPI profiles. This led Driscoll to speculate that the prison environment fosters modes of adaptive behavior that are viewed as maladaptive behaviors outside of prison. Erikson and Roberts (1966; 3) initially compared a maladjusted juvenile delinquent group to an adjusted group, and they found that the maladjusted group scored significantly higher on the *Pd* scale. They generated a 19-item scale that differentiated the two groups, but two replication attempts failed to support any of their initial findings. Lefkowitz (1966; 1) compared adjustment "failures" with adjustment "successes" and found that the failure group scored significantly higher on the *Ma* scale. Twomey and Hendry (1969; 2) compared discipline problem inmates with a comparison group and found that the discipline problem group scored significantly higher on the *L, F, Hs, D, Hy, Mf, Pa, Pt, Sc,* and *Si* scales. Snortum, Hannum, and Mills (1970; 1) rated a group of women offenders on a continuum representing frequency of rule violations and discovered that frequency of rule violations positively correlated with elevations on the *Pd* and *Ma* scales. Two of these studies (Driscoll, 1952, and Snortum et al., 1970) obtained their MMPIs before the disciplinary problems occurred, whereas the rest were obtained after the research groups had been formed.

None of the predictive studies discussed later considered the base-rate probability of their criterion variable, which was most commonly some indicator of disciplinary actions taken. Although these base-rate statistics are probably not routinely gathered, Meehl and Rosen (1955) suggest that a simple analysis of available records would produce a suitable base rate for comparative purposes. It is recommended that future studies rectify this observed methodological flaw.

Predictive studies have investigated the ability of experimental scales to identify potential disciplinary problems. Panton (1958; 2) generated the 36-item Prison Adjustment Scale (*Ap*) and examined its discriminative powers on the profiles of two adjusted inmate groups, two nonadjusted groups and

one severely nonadjusted group. The scale correctly identified 82% of each adjusted group, 87% and 85% of the two nonadjusted groups, and 93% of the severely nonadjusted group. Pierce (1972c; 1) compared inmates with two or more infractions to a comparison group and found that Panton's cutoff scores identified 88% of the maladjusted inmates but produced a false-positive rate of 50%. Edwards (1963; 1) compared groups of first-offender juvenile "successes," first-offender juvenile "failures," and prison inmate "failures" on the conventional scales, the Harris-Lingoes subscales (Harris & Lingoes, Note 8), 14 experimental scales (including *Ap*), and mean number of high-point elevations. He found that the prison inmate failure group scored significantly higher than the juvenile groups on the *Sc* scale and the *Sc2A* subscale but found no other differences. (This may be partially due to a small *N*.)

Wattron (1963; 1) compared parole and maladjusted inmates and generated the Prison Maladjustment Scale (*PM*). This scale successfully identified 82% of the maladjusted group and 84% of the parolees in his cross-validation sample. Stump and Gilbert's (1972; see the section on Prison Escape) previously cited study compared the *Ap* scale scores of a group of inmates repeatedly disciplined by solitary confinement with the *Ap* scale scores of a group that had spent no nights in solitary confinement, but this produced no significant differentiation. Panton (1973; 2) compared a group of management problem inmates with a large baseline inmate sample and examined the conventional scales, his Prison Classification Inventory (PCI; Panton, Note 9), modeled after the conventional MMPI profile sheet, consisted of the following conventional and experimental MMPI scales: *L, F, K, Ap, Ec, HC, PaV, Hsx, A, R, Pd*, Defect of Inhibition Control (*Dc&i*), Sensorimotor Dissociation (*SD*), and *Asx*, the Harris-Lingoes subscales and five additional experimental scales. He found that the management problem inmates scored significantly higher than the baseline sample on the *F, Pd, Pd2, Mf, Ma, Ma1, Ap, Ec, HC*, and *Re* scales, and these inmates scored significantly lower on the *Hs, Pt, Si, A*, and *R* scales. Panton noted that the management problem inmates exhibited uniformly poor prognostic MMPI signs (high scores on the *Pd, Ma*, and *HC* scales and low scores on the *Hs, D, Pt*, and *A* scales), and he concluded that their susceptibility to rehabilitative efforts "appears limited."

Sutker and Moan (1973; 1) examined differences on the conventional scales and the *Ap* and *PM* experimental scales between two successive pairings of groups of "bad actors" (severe discipline-problem inmates) and "no disciplines." Their first group of bad actors scored significantly higher than the no disciplines on the *F, Ma*, and *PM* scales, whereas the second group of bad actors scored significantly higher on the *F, Hy*, and *Ma* scales. They noted that both no-disciplne groups actually scored higher on the *Ap* scale than their bad-actors counterparts, although the differences were not significant. Two of these studies (Panton, 1973; Sutker & Moan, 1973) obtained MMPI profiles after the criterion and comparison groups were formed, whereas the rest of the studies obtained their MMPIs before the discipline problems occurred.

One study was found that examined self-mutilating prisoners. Panton (1962a; 1) compared a group of self-mutilators with a group of model prisoners and a group of infraction-nonmutilators on the conventional scales and eight experimental scales. The infraction-nonmutilators were matched with the self-mutilator group "as to number and type of infraction and degree of exposure to custodial stress and pressure" (p. 63). The infraction-nonmutilator group scored significantly higher than the model prisoners group on the *Ap* scale only. The self-mutilator group scored significantly higher than the other two groups on the *F, Pa, Pt, Sc*, Anxiety Index (*AI*), Critical Item (*CI*), Inner Madadjustment (*In*), Judged Manifest Hostility (*Jh*), and Psychotic Tendency (*Pq*) scales and significantly lower on the Conversion Reaction (*CR*) scale. The self-mutilator group also scored significantly higher than the model prisoners group on the *Pd* and *Ap* scales. Panton concluded that "the self-mutilators were more inclined toward

compulsive outbursts of hostility, appeared more anxious, expressed a greater inner turmoil, and appeared more inclined toward bizarreness in their overt resistance to stringent attempts to control their aggressiveness" (p. 66). Panton then generated the Self-Mutilator scale (*SM*) by adding the *T* scores of the *F*, *Pa*, and *Sc* scales together and determining a cutoff score. This scale identified 83.8% of the self-mutilators, 75.6% of the model prisoners, and 81.2% of the infraction-nonmutilators in his original sample.

In this latter study, Panton (1962a) notes that with respect to the self-mutilators, "none of the group claimed they were actually attempting to destroy themselves nor did the psychiatric examinations reveal any evidence in support of suicidal intentions" (p. 63). No other studies were found that even made reference to suicidal prisoners. This lack of suicide research in prisons is difficult to explain, especially since attempted suicides constitute a dangerous problem for both administrative and treatment personnel. Generalization of suicide research results from other populations (e.g., mental hospitals) is an unwarranted procedure, and in any case such generalization is no substitute for findings that are based on prison populations. This important issue demands exploratory research on the MMPI profiles of suicidal prisoners, since the ability to effectively identify suicidal risks in an economical manner would obviously be of great value to prison personnel. Although the overall incidence of suicidal attempts is probably small, Meehl and Rosen (1955) point out that their base-rate considerations sometimes cease to be relevant, especially in certain "life-and-death" situations; surely a moderate rate of false positives in suicidal risk prediction is an acceptable price to pay for the trade-off in preserved human lives.

Those studies that focused on the conventional MMPI scales have only come up with inconsistent and inconclusive results. This may be partially due to different criteria for the formation of criterion groups, different timing of MMPI administrations, and the different populations that were examined. More well-controlled MMPI research may yet offer valuable dynamic insights into the reasons behind maladjusted behavior in some prison inmates. Panton's *Ap* scale has not yet proven useful in other parts of the country, although he has consistently obtained positive results with this scale in North Carolina; again, differences across studies with respect to timing of MMPI administration, criteria for the formation of criterion groups, and different types of prison populations may partially account for this lack of consistency. Wattron's *PM* scale needs further research, since the only attempted cross-validation obtained significant results in just one of two comparisons. Other potentially valuable indices such as the Harris-Lingoes subscales, Panton's PCI, and Panton's *SM* scale also need further investigation before any conclusions about their worth can be drawn. This entire area merits further study, since effective predictors of potential prison adjustment problems would be invaluable to both administrative and treatment personnel. Groups differentiated along such dimensions could be placed within the prison so as to minimize potential disturbances, and treatment plans individually geared to such differentiated groups could bring an increase in positive rehabilitation results. Future research should attempt to cross-validate existing MMPI indicators and should consider the generation of new experimental scales that may prove to be more effective than existing ones. The lack of research on the MMPIs of suicidal risk prisoners constitutes a glaring omission in this research area that should be rectified immediately.

MMPI Differences Across Race and Sex

Racial differences. Several studies have examined the differences in conventional scale elevations produced by groups of black and white inmates. Stanton's (1956) previously cited study (see the section on First Offenders Versus Recidivists) initially compared groups of black and white inmates and found no significant differences. Caldwell (1959; 2) pursued a similar design and found that black inmates obtained significantly higher scores on the *Hs*, *D*, *Mf*, *Pa*,

and *Ma* scales and significantly lower scores on the *Pd* scale. Panton's (1959a) previously cited study (see the section on First Offenders Versus Recidivists) found that black inmates scored significantly higher than white inmates on the *F, Pa, Sc,* and *Ma* scales and significantly lower on the *Hy* scale. As part of a larger study, Costello, Fine, and Blau (1973; 1) found no significant differences between their samples of black and white inmates. Elion and Megargee (1975; 3) investigated the validity of the *Pd* scale among black males using groups of prisoners and groups of college students. They found that black inmates scored significantly higher on the *Pd* scale than both a group of "culturally deprived black male university students" and a group of white inmates. They concluded that elevations on the *Pd* scale validly express levels of social deviance among young black males but that the present scale norms appear to show racial bias.

A few studies have examined black–white differences with respect to experimental scales. Panton (1959b; 2) compared black and white inmates on the Harris-Lingoes subscales and found that black inmates scored significantly higher on the Ideas of External Influence (*Pa1*), *Sc1A,* and *Ma4* subscales and significantly lower on the *Pd2* subscale. Haven (Note 10; 1) investigated racial differences on Megargee's *O-H* scale and found that black inmates scored significantly higher than white inmates, suggesting either that black inmates as a group experience more feelings of social alienation or that they have been shaped by societal pressure to more actively inhibit aggression. (Haven favored the latter alternative.) As part of a larger study, Fisher (1969; 1) investigated racial differences on the Repression-Sensitization (*R-S*) scale and found that white inmates scored significantly higher than their black counterparts, suggesting that the black inmates showed evidence of more repression.

More recent studies have directly confronted the issue of racial and cultural bias in the MMPI with their comparisons of prisoners from different racial and cultural groups. McCreary and Padilla (1977) compared 40 black, 36 Mexican American, and 267 white male misdemeanor offenders who had been convicted and were awaiting sentencing. They compared individual scale elevations as well as scores on Goldberg's (1965) linear classification system and ran unmatched comparisons as well as comparisons in which subjects were matched on educational level and occupation. They hypothesized that differences due to socioeconomic factors would appear only in the unmatched comparisons, whereas differences due to cultural factors would appear in both comparisons. Analyses were conducted using only valid profiles (less than 30 items left blank, *F* scale less than a raw score of 23, and the *F-K* index less than 11) and using all profiles, but there were virtually no differences in the results of these two analyses, so valid profile results were used to report most findings. Mexican Americans had significantly less education than whites, but no other significant differences emerged with respect to educational level or occupation. In the unmatched comparisons, blacks were significantly higher on the *Al* scale and significantly lower on the *Hy* and *Mf* scales than whites. Mexican Americans were significantly higher on the *L, Hs,* and *O-H* scales than whites. (They were also higher on the *K* scale when all profiles were used.) In the matched comparisons, blacks scored significantly higher on the *K* and *Ma* scales and significantly lower on the *Hy* scale than whites. (Only the *Ma* scale difference remained significant when all profiles were used.) The Mexican Americans scored higher on the *L, K,* and *O-H* scales than whites. The only significant difference on the Goldberg indices showed that on the psychiatric–sociopathic index, the Mexican Americans scored in the psychiatric range, whereas the whites scored in the sociopathic range (unmatched condition). McCreary and Padilla concluded that both cultural and socioeconomic factors seemed to contribute to the observed MMPI differences between these three groups.

Rosenblatt and Pritchard (1978) compared 104 black and 191 white male inmates on the MMPI with respect to differences on full-scale WAIS IQ scores. They rejected number of years in school as an appropriate indicator of educational achievement because

most of their sample of Mississippi inmates had been educated in segregated schools that were not considered to be equivalent in educational quality. They divided their sample into four subgroups with respect to race and IQ (using the overall sample's mean IQ of 93 to divide the groups). They found no racial differences between the high-IQ groups but found that the low-IQ blacks ($N = 81$) scored significantly higher on the *Hs*, *Sc*, and *Ma* scales and significantly lower on the *Hy* scale than the low-IQ whites ($N = 70$). Successive applications of more stringent validity rules did not affect these findings. Rosenblatt and Pritchard concluded that racial differences on the MMPI seem to be limited to low-IQ subjects.

The findings on the conventional scales are not definitive at this time. The most consistent finding appears to be a higher elevation for blacks than whites on the *Ma* scale (five studies, including Panton's Harris-Lingoes subscales findings), with a similar but weaker trend on the *Sc* and *Pa* scales (three studies each, all of which included Panton's Harris-Lingoes subscale findings) and the *Hs* scale (two studies). Blacks also seem to occasionally score lower than whites on the *Hy* scale (three studies) and the *Mf* scale (two studies). Only Elion and Megargee (1975) found significantly higher elevations for black inmates on the *Pd* scale, whereas significant differences in two other studies (including Panton's Harris-Lingoes subscale findings) showed white inmates scoring significantly higher on the *Pd* scale. None of the findings for the experimental scales have been replicated. The most crucial findings here appear to be the results of Rosenblatt and Pritchard (1978), which tend to support the position on racial bias in the MMPI (discussed in the Sources of Variance and Their Effects on Test Results section). Apparent racial bias in the MMPI may actually be due to educational factors, since more intelligent blacks do not seem to display the differences in MMPI performance that less intelligent groups of blacks display. More research is definitely needed to resolve the issue of racial and cultural bias in the MMPI, and such efforts should investigate the differences between black and white MMPI inmate protocols with respect to education and/or IQ.

Sex differences. Research with the MMPI in prison populations has been conducted almost completely with male inmates. Only two of the studies reviewed previously (Davis, 1971; Snortum et al., 1970) used female inmate populations. Although there are far fewer female inmates than male inmates in the United States today, the female inmate population "presents a significant minority whose needs in terms of proper classification, treatment and training are as great as the needs of their more numerous male counterparts" (Panton, 1974). Two studies were found that compared samples of male and female prison inmates. Panton (1974; 2) examined differences on conventional scales and the Harris-Lingoes *Pa* subscales and found that female inmates scored significantly higher than male inmates on the Poignancy (*Pa2*) and *Si* scales and scored significantly lower on the *Hs* and *D* scales. Panton concludes that male inmates "appear to be more anti-social with neurotic overlays," whereas the female inmates "appear more asocial than anti-social with overlays of greater emotional sensitivity" (p. 332). Joesting, Jones, and Joesting (1975; 1) examined differences on the conventional scales and seven experimental scales and found that female inmates scored significantly lower than male inmates on the *F*, *Hs*, *D*, *Hy*, *Pd*, *Mf*, *Pa*, *Sc*, *Ma*, *Si*, *Ec*, *A*, *R*, *Pd1*, *Dc&i*, and *SD* scales, and scored significantly higher on the *K* and *Ap* scales. They concluded that the males appeared more emotionally disturbed than the females. Although certainly lacking in consistency, both of these studies suggest significant MMPI protocol differences between male and female prison inmates that preclude the generalizability of the research findings in this article to female inmate populations. Attempted replication of these male inmate findings with female inmate populations is the only possible solution to this problem.

Panton (1976; 2) compared a group of male prisoners admitted in 1966 to a group of male prisoners admitted in 1971 to investigate any population changes over time on the *Mf* scale and the Pepper and Strong

(Note 11) *Mf* subscales. He found that the 1971 group scored significantly higher on the *Mf*, *Mf1*, and *Mf5* scales, and concluded that the 1971 sample showed "a greater personal and emotional sensitivity and a more frequent rejection of masculine occupations and avocations" (p. 606) than their 1966 counterparts. This finding needs replication but suggests that considerable caution should be employed in applying any of the findings concerning the *Mf* scale that were discussed in this review. Although the essential meanings of these findings are probably not affected, any *T*-score levels employed for interpretive purposes may be anachronistic and therefore misleading.

Conclusions and Recommendations

The studies covered in this review can most accurately be described as a beginning effort in the attempt to maximize the usefulness of the MMPI in corrections. As mentioned in the introduction, these findings are best viewed as indicative of the potential of the MMPI in prison work, not as a final judgment of its worth. Since the overall representativeness of the experimental samples employed was often restricted, and several methodological shortcomings were apparent, the generalizability of the present findings is limited. The issue of racial and cultural bias in the MMPI with respect to prison populations in particular is a vital question that demands extensive research in it's own right, since at present one cannot determine with an acceptable degree of certainty just what a minority group member's MMPI means and does not mean. No legitimate inferences can be generalized from the present findings to women inmates, and the effects of age and IQ will probably modify interpretations somewhat when the nature of these effects is more precisely defined. A strong note of caution is necessary with respect to the appropriate use of this test: The MMPI serves as a source of probabilistic clinical statements that are hypotheses for further exploration, and employment of the MMPI as the sole basis for any kind of decision effecting the life of a subject constitutes a serious abuse of the test. This is because the "noise" inherent in any test of this type always creates the danger of false positive conclusions, and as a result the MMPI should be used in conjunction with other sources of data to form the basis of important decisions affecting a subject's welfare if it is to be employed in an enlightened and ethical manner. In any event, these initial research findings do appear to be promising. Further research is necessary for a conclusive assessment of the MMPI's potential for becoming an important and valuable aid in correctional practice that would benefit the inmate as well as the correctional personnel responsible for effective program functioning.

The MMPI shows potential in several areas. The findings concerning the *O-H* experimental scale and the 4-3 prototype possess a strong preliminary research base that needs cross-validation; however, evidence is sufficiently strong at this point to warrant the provisional application of these indicators in correctional practice as warning signs of potentially dangerous violent outbursts. Several other findings appear promising but need further study. For example, the identification of homosexuality with the MMPI could be profitably employed in administrative and treatment decisions after some further exploration and refinement of the present findings. The classifications of psychopathologic behavior described previously could also be of great use to administrative and treatment personnel if expanded by further study. The *Rmn* experimental scale and index demands instant examination, for it could prove to be a highly effective predictor of recidivism that could substantially improve hit rates over chance prediction. Finally, the pursuit of the findings of Megargee (1977) and his associates may prove to be more fruitful than can be presently imagined. Inconclusive findings exist on indicators of institutional adjustment, but the MMPI could yet prove to be worthwhile in this area. The identification of suicide risks in prison has been inexplicably ignored to date and demands immediate exploration. Areas investigated in which the MMPI appears to be of little present worth include the post hoc comparison of first offenders versus recidivists and

the identification of addictions and escape risks. In short, further research on the MMPI's use in several of these areas could produce results that would prove to be invaluable to correctional personnel.

In 1970, Haven (Note 1) stated that "an overview of all the research reviewed gives the rather discouraging picture of a hodgepodge of one-shot investigations. There were few follow-ups and little cross-evaluation of previous findings" (p. 39). Unfortunately, this still seems to be largely true 7 years later. With the two outstanding exceptions of Panton and Megargee, there is no evidence of any concerted effort at comprehensive longitudinal study with thorough follow-up procedures for the MMPI's use in prison work. Such efforts are sorely needed and can be instigated by the routine testing of prison admissions with the full 566-item MMPI to build up a data bank. However, inspection of Table 2 reveals that approximately two-thirds of the studies reviewed seem to have drawn their MMPIs from just such a data bank; the lack of well-controlled longitudinal research becomes increasingly difficult to justify in the light of this fact. A few selected areas such as recidivism may be more profitably investigated with MMPIs administered long after initial admission, yet the comparison of such protocols with the corresponding admissions protocols across the criterion and comparison groups could in itself provide dependable indices of specific inmate behaviors. In summary, more longitudinal research with thorough follow-up procedures is needed if effective investigation of the MMPI's potential in corrections is to be realized.

Past methodological shortcomings must be eliminated if future results are to prove fruitful. Future research must observe either standard random sampling procedures or standard matching procedures if their findings are to be representative; the presence of a large MMPI data bank should facilitate the meeting of these requirements. Investigators must also instigate better controls or post hoc checks for variables such as age, race, and IQ to maximize the representativeness and generalizability of their results. In fact, these and several other design aspects (such as *F* scale elevations, fake-good and fake-bad indicators, and the several remaining subject characteristics listed in Table 2) demand further research in their own right to produce methodological refinements that should increase the MMPI's sensitivity to significant differences. One of the most important improvements that needs to be made over previous predictive research is the incorporation of Meehl and Rosen's (1955) essential guidelines prescribing the consideration of base-rate probabilities. The different approaches to MMPI data interpretation discussed in the Methodology section should also be kept in mind, since the simultaneous investigation of more than one of these approaches may produce unexpectedly valuable findings. Once again, longitudinal research with thorough follow-up procedures is a must. Future researchers who incorporate these important guidelines into their experimental designs will maximize both their ability to detect actual significant differences and the generalizability of their findings.

The central purpose of this review has been to stimulate needed cross-validation of existing findings as well as to encourage further exploratory research with the MMPI in prison work. In addition, it is hoped that the interfacing of these findings with the ongoing exploration of the new classification system of Megargee (1977) and his associates will enhance the precision and productivity of the MMPI's employment in corrections. The full extent of the MMPI's ultimate usefulness in this respect cannot yet be fully appreciated, but its potential should not be underestimated at this point. The MMPI may someday prove to be an indispensable factor in the creation of more effective rehabilitative approaches to correctional practice.

Validity Conditions in Repeated Measures Designs

Huynh Huynh and Garrett K. Mandeville
College of Education
University of South Carolina

This article has two objectives. The first is to present necessary and sufficient conditions for the validity of traditional within-subject F tests in repeated measures designs. It is shown that the Mauchly sphericity criterion (W) and possibly the Box test for the equality of covariance matrices are appropriate to judge the validity of these conditions. Valid applications of both tests are conducted on sets of orthogonal normalized variables that are associated with each cluster of within-subject mean square ratios. The second objective of the article is to present empirical results on the appropriateness of using the W criterion when the variates are not normally distributed. For light-tailed distributions, the W criterion was shown to be moderately conservative, whereas for heavy-tailed distributions, empirical Type I error rates exceeded nominal alpha. Since most social science applications typically involve light-tailed rather than heavy-tailed distributions, the W criterion should provide useful results in most cases.

Traditional univariate analyses of variance for repeated measures (or mixed model) designs are used extensively in educational and psychological research (Kirk, 1968; Winer, 1971). In most situations observations are made on each subject in the sample under each combination of conditions (the within-subject factors). For example, a developmental psychology study may require measurements at several time intervals, with alternate forms used at each point in time. Thus, Time and Form would constitute two within-subject factors. If no factors that differentiate subjects are included, the design implies the testing of three within-subject hypotheses dealing with the effects of Time, Form, and the Time × Form interaction. Corresponding to each of these effects is a (nonunique) set of orthogonal normalized (orthonormal) variables.

On the other hand, if the subjects are stratified on one or more independent (between-subjects) factors, the interaction of these factors and the repeated measures factors provides more within-subject hypotheses that are subject to testing. In general, however, all within-subject hypotheses may be grouped into clusters that are tested using a common error term. In the example, if subjects were categorized according to age level, the mean squares associated with Time and the Age × Time interaction would be tested against the Time × Subject-Within-Age error term. The second cluster of hypotheses deals with Form and the Age × Form interaction, and the last group focuses on the interactions Time × Form and Time × Form × Age. As in the case of no independent factors, each of these clusters of effects and the error terms against which they are tested are associated with a set of orthonormal variables. These variables remain unchanged regardless of whether the subjects are subdivided into independent categories or not. As is discussed later, within normal distributions only the orthonormal variables will play a role in the validity of the traditional univariate F tests for repeated measures designs similar to the layout in the developmental psychology example.

A confusion exists regarding the validity conditions for the within-subject F tests in

Requests for reprints should be sent to Huynh Huynh, College of Education, University of South Carolina, Columbia, South Carolina 29208.

repeated measures designs. Originally these tests were derived from models implying equal variances and equal covariances (the compound symmetry condition) for the repeated measures (Scheffé, 1959). Several textbooks and articles written in the 1960s or earlier (Collier, Baker, Mandeville, & Hayes, 1967; Kirk, 1968) tended to treat compound symmetry as the required (e.g., necessary and sufficient) condition for the validity of the within-subject F tests. Huynh and Feldt (1970) and Rouanet and Lepine (1970), however, have shown that compound symmetry is only a sufficient condition. Although counterexamples are illustrated in Huynh and Feldt (1970), authors of more recent textbooks (Ferguson, 1976; Keppel, 1973), articles (Davidson, 1972; Poor, 1973), and computer manuals (Nie & Hull, Note 1) still mistake compound symmetry as a sine qua non assumption for the F tests.

Confusion also persists in statements regarding the validity conditions for designs with between-subjects (independent) factors. Huynh and Feldt (1970, Theorems 2 and 4) prove that these conditions involve only the orthonormal variables and give a counterexample, showing that it is unnecessary to assume equality of covariance matrices for the repeated measures across the independent factors. The latter condition is quoted in several design textbooks (Keppel, 1973; Winer, 1971, p. 523). To resolve this confusion, the next section of this article discusses the conditions under which the traditional within-subject F tests in repeated measures designs are valid.

Description of the Validity Conditions

The validity conditions under normality for the within-subject F tests have been investigated by Huynh and Feldt (1970) for randomized block (one-factor repeated measures) designs and for simple split-plot designs (two-factor designs with repeated measures on one factor), by Rouanet and Lepine (1970) for randomized block designs, by Mendoza, Toothaker, and Cain, (1976) for three-factor designs with repeated measures on two factors, and by Huynh (1978) for complex designs involving both independent and repeated factors. In the most general terms, the mean square ratios in each cluster of hypotheses follow exact F distributions if and only if (a) the covariance matrices for the associated set of orthonormal variables are identical across all levels of the independent factors, and (b) the common covariance matrix has a sphericity pattern (i.e., equal variances and zero covariances). If there are no independent factors, then the first condition does not apply. It may be noted that both conditions are based on the orthonormal variables and not on the original repeated measures. Therefore, they are more general than the requirements of equality of the covariance matrices for the original repeated measures and of compound symmetry for the common matrix. The remainder of this section displays the necessary and sufficient conditions for four typical situations.

Case 1: One-Factor Designs With Repeated Measures on the Factor

Assume that all subjects are measured under the b levels of the repeated factor B, and let the vector $\mathbf{X} = (\mathbf{X}_1, \mathbf{X}_2 \ldots, \mathbf{X}_b)'$ be the observation vector. Let $\mathbf{M}$ be any $(b-1) \times b$ matrix of $(b-1)$ orthonormal row vectors. Then $\mathbf{Y} = \mathbf{MX}$ transforms the b original variables to $(b-1)$ orthonormal variables. For example, if $b = 4$, the matrix $\mathbf{M}$ may be taken as follows:

$$\mathbf{M} = \begin{bmatrix} 1/(2)^{\frac{1}{2}} & -1/(2)^{\frac{1}{2}} & 0 & 0 \\ 1/(6)^{\frac{1}{2}} & 1/(6)^{\frac{1}{2}} & -2/(6)^{\frac{1}{2}} & 0 \\ 1/(12)^{\frac{1}{2}} & 1/(12)^{\frac{1}{2}} & 1/(12)^{\frac{1}{2}} & -3/(12)^{\frac{1}{2}} \end{bmatrix}.$$

Let $\Sigma(\mathbf{X})$ be the covariance matrix of $\mathbf{X}$. Then the covariance matrix of $\mathbf{Y}$ is $\Sigma(\mathbf{Y}) = \mathbf{M}\Sigma(\mathbf{X})\mathbf{M}'$. Within normal distributions, the mean square ratio for the B effects follows an exact F distribution if and only if $\Sigma(\mathbf{Y}) = \lambda\mathbf{I}_{b-1}$, $\mathbf{I}_{b-1}$ being the identity matrix of order $(b-1)$. In other words, the $(b-1)$ orthonormal variables $\mathbf{Y}$ are independent and equally variable, that is, the sphericity pattern holds.

Case 2: Two-Factor Designs With Repeated Measures on One Factor

Suppose that the subjects in Case 1 are categorized into a levels of an independent

	1/6	1/6	−2/6	1/6	1/6	−2/6	−2/6	−2/6	4/6

(between-subjects) factor A. The within-subject hypotheses regarding the B and AB effects share the same error term. Thus, they belong to one cluster, and the corresponding orthonormal variables are defined by the **Y** vector of Case 1. Let $\Sigma_i(\mathbf{Y})$, $i = 1, \ldots, a$ be the covariance matrices of **Y** for the a levels of Factor A. The B and AB mean square ratios follow exact F distributions if and only if (a) the $\Sigma_i(\mathbf{Y})$ matrices are identical, and (b) the common covariance matrix has the sphericity pattern.

Case 3: Two-Factor Designs With Repeated Measures on Both Factors

Consider now a $B \times C$ two-factor design in which both B and C are repeated factors. This corresponds to the developmental psychology study described previously in which all subjects are pooled together in one group. There are three within-subject mean square ratios—one for the B effects, one for the C effects, and one for the BC interactions. Each corresponds to a set of orthonormal variables, namely $\mathbf{Y}_B$ for B, $\mathbf{Y}_C$ for C, and $\mathbf{Y}_{BC}$ for BC. (See Table 1 for an illustration.) Mendoza et al. (1976) show that each mean square ratio has an exact F distribution if and only if the corresponding orthonormal variables are independent and equally variable. Hence, the F test for B is valid if and only if $\Sigma(\mathbf{Y}_B) = \lambda_B \mathbf{I}_{b-1}$. The F test for C requires that $\Sigma(\mathbf{Y}_C) = \lambda_C \mathbf{I}_{c-1}$, and the F test for BC demands that $\Sigma(\mathbf{Y}_{BC}) = \lambda_{BC} I_{(b-1)(c-1)}$. In these conditions, the constants λ_B, λ_C, and λ_{BC} need not be equal.

Case 4: Three-Factor Designs With Repeated Measures on Two Factors

Finally let $A \times B \times C$ be a three-factor design in which A is the independent (between-subjects) factor and both B and C are repeated (within-subject) factors. The within-subject mean square ratios are then grouped into the following three clusters: the B and AB effects, the C and AC effects, and the BC and ABC effects. Each cluster corresponds to a set of orthonormal variables defined as in Case 3 (e.g., as if there were no independent factor). Let $\Sigma_i(\mathbf{Y}_B)$, for example, be the covariance matrix of the $\mathbf{Y}_B$ orthonormal variables at the ith level of factor A. Then the two mean square ratios for B and AB follow exact F distributions if and only if (a) the $\Sigma_i(\mathbf{Y}_B)$ matrices are identical, and (b) the common covariance matrix has a sphericity pattern. Similar necessary and sufficient conditions hold for the other two clusters of mean square ratios.

Testing for Sphericity

As indicated in each case of the previous section, the validity of the within-subject F tests requires sphericity for some covariance matrix. The matrix may be either the covariance matrix of a suitably chosen set of orthonormal variables or the common covariance matrix, if the design has some between-subjects factor(s). Thus, a test for sphericity is required if preliminary testing is to be considered.

Let the p-component vector $\mathbf{Y}$ be normally distributed with unknown mean vector and covariance matrix $\Sigma(\mathbf{Y})$. The assumptions of independence and variance homogeneity for the p components of $\mathbf{Y}$ are equivalent to the condition that $\Sigma(\mathbf{Y}) = \lambda \mathbf{I}_p$, where $\mathbf{I}_p$ is the identity matrix of order p. Our interest is in testing the above condition as a null hypothesis (H_0) against the alternative hypothesis H_1: $\Sigma(\mathbf{Y}) \neq \lambda \mathbf{I}_p$. Let $\Sigma(\mathbf{Y})$ be estimated by the sample covariance matrix $\mathbf{S}$ based on a random sample of n vectors. Then the likelihood ratio test for H_0 against H_1 is of the form $W = |\mathbf{S}|/|\text{trace } \mathbf{S}/p|^p$ (Mauchly, 1940). The exact sampling distribution of W has been provided by Consul (1967, 1969), Pillai and Nagarsenker (1971), Mathai and Rathie (1970), and Nagarsenker and Pillai (1972, 1973; these also provide tables of critical values for W).

In the context of repeated measures designs, the matrix $\mathbf{S}$ is the sample covariance matrix of each set of orthonormal variables if there are no independent factors (Cases 1 and 3). For designs with independent factor(s), $\mathbf{S}$ is taken as the pooled covariance matrix if the assumption of equal covariance matrices for the orthonormal variables is tenable (Cases 2 and 4).

Testing for Equality of Covariance Matrices

As illustrated in Cases 2 and 4, suitably chosen sets of orthonormal variables must share the same covariance matrix across the independent factors for the corresponding within-subject mean square ratios to follow exact F distributions. Within normal distributions, equality of covariance matrices may be tested via the Box modified likelihood ratio criterion M (Morrison, 1976; Timm, 1975; Winer, 1971). Let p be the number of orthonormal variables and k be the number of levels of the independent factor. Let $\mathbf{S}_i$ be the traditional unbiased estimate of Σ_i, associated with the ith level of the independent factor and based on n_i degrees of freedom. Then the hypothesis $\Sigma_1 = \ldots = \Sigma_k$ may be tested via the Box criterion:

$$M = \Sigma n_i ln|\mathbf{S}| - \sum_{i=1}^{k} n_i ln|\mathbf{S}_i|,$$

where

$$\mathbf{S} = \sum_{i=1}^{k} n_i \mathbf{S}_i / \Sigma n_i$$

is the pooled estimate of the common covariance matrix. If

$$\rho = 1 - \frac{2p^2 + 3p - 1}{6(p+1)(k-1)}\left(\Sigma \frac{1}{n_i} - \frac{1}{\Sigma n_i}\right),$$

then ρM approximately follows a chi-square distribution with $(k-1)p(p+1)/2$ degrees of freedom if the condition of equality of the covariance matrices holds. Tables of critical values of M at the .05 level may be found in Korin (1969) or Pearson and Hartley (1972) for the case of equal sample size.

To test the validity conditions in the presence of independent factors, a two-step procedure is suggested. First, the Box test may be carried out for suitably chosen sets of orthonormal variables. If equality of covariance matrices is tenable, then the Mauchly test for sphericity may be carried out on the pooled estimate $\mathbf{S}$ of the common covariance matrix. If α is the (joint) probability of the Type I error of the two-step procedure, then each step may be performed at the $\alpha/2$ level of significance. The two following sections present numerical illustrations for Cases 3 and 4.

Numerical Examples

Example 1

Table 2 presents the basic data for 22 subjects in a $B \times C$ design with repeated measures on both B and C. Table 1 displays the

coefficients defining the orthonormal variables associated with the within-subject effects B, C, and BC. Let $\mathbf{S(X)}$ be the unbiased estimate of the covariance matrix of the nine repeated measures. Then the sample covariance matrices of the orthonormal variables associated with B, C, and BC are, respectively,

$$\mathbf{S}(\mathbf{Y}_B) = \mathbf{M}_B\mathbf{S}(\mathbf{X})\mathbf{M}'_B,\ \mathbf{S}(\mathbf{Y}_C) = \mathbf{M}_C\mathbf{S}(\mathbf{X})\mathbf{M}'_C,$$

and $\mathbf{S}(\mathbf{Y}_{BC}) = \mathbf{M}_{BC}\mathbf{S}(\mathbf{X})\mathbf{M}'_{BC}$. The corresponding sphericity criteria are $W_B = .9921$, $W_C = .9923$, and $W_{BC} = .5055$. At the .05 level of significance, the critical values are .7411, .7411, and .4173, respectively. Since large values of W support the sphericity assumption, the data indicate that the validity conditions for the B, C, and BC traditional F tests are tenable.

Example 2

The 22 subjects of Table 2 are now assigned to two levels of the independent factor A. The first level consists of the first 10 subjects, and the second level has 12 subjects. The orthonormal variables associated with the clusters of within-subject effects (B, AB), (C, AC), and (BC, ABC) are defined by the matrices $\mathbf{M}_B$, $\mathbf{M}_C$, and $\mathbf{M}_{BC}$ as in Numerical Example 1. The Box criteria for equality of covariance matrices are, respectively, $M_B = 2.4626$, $M_C = 1.7064$, and $M_{BC} = 10.2912$. The critical values at the .025 level of significance are $\rho_B\chi^2(3) = .8902 \times 9.3484 = 8.3219$ for M_B and M_C, and $\rho_{BC}\chi^2(4) = .7821 \times 11.1433 = 8.7152$ for M_{BC}. The Box criteria are thus small enough to support the presumption of equal covariance matrices across the two levels of A for each of the three sets of orthonormal variables $\mathbf{Y}_B$, $\mathbf{Y}_C$, and $\mathbf{Y}_{BC}$.

The preliminary testing may now proceed to the hypothesis of sphericity for each common covariance matrix. The Mauchly criteria for the clusters (B, AB), (C, AC), and (BC, ABC) are .9912, .9780, and .4846, respectively. It may be noted that under the assumption of equality of the covariance matrices, each pooled sample covariance matrix with 20 degrees of freedom may be considered

to be based on a random sample of 21 subjects. By entering the value of $N = 21$ in the tables of Nagarsenker and Pillai (1972), the interpolated critical values at the .025 level are .6776 for the first two clusters and .3542 for the last cluster. Hence, the assumption of sphericity holds for each set of orthonormal variables.

In summary, the data analysis (at the joint .05 level of significance) indicates that assuming normality, the validity conditions for the traditional within-subject F tests hold for the data of this numerical example.

Effect of Nonnormality on the Mauchly Test

As indicated previously, the Mauchly test is appropriate in all cases to check the validity of the traditional testing procedure. Being by construction a *LR* criterion test, W may be suspected to be oversensitive to departure from normality. This is known to occur for various *LR* tests of variance homogeneity such as the Bartlett test and two of its competitors, the Hartley $F_{\max}$ and the Cochran criteria (Scheffé, 1959; also see Games, Winkler, & Probert, 1972, for a list of references). On the other hand, there are indications that least squares procedures (which are equivalent to *LR* methods in some situations) are fairly robust when the populations involved have light tails (Hogg, 1974; Tukey & McLaughlin, 1963, p. 332). As noted by Hogg, there are many practical situations in which distributions are inherently light tailed. This is particularly true in the social sciences if the measuring instrument has modest floor and ceiling effects. However, data may contain outliers that tend to shift the density toward the tails, thus creating situations in which tails are heavier than that of the normal distribution. Since the F test for means is fairly insensitive to the shape of the parent distributions and since the W criterion may be used to determine the tenability of the F test, it is desirable to explore the effect of nonnormality on W. The remainder of this article focuses on the Type I error rate associated with the W criterion under several instances involving light-tailed distributions, heavy-tailed distributions, and mixtures of normal distributions. These results were obtained using the technique of computer simulation for situations in which the p components of the vector $\mathbf{X}$ were independent and had the same distribution. For normal distributions, the standardized fourth moment (β_2, a measure of kurtosis) = 3. Light-tailed distributions correspond to $\beta_2 < 3$ and heavy-tailed distributions to $\beta_2 > 3$.

Selection of Common Distributions (Component Distributions)

Eight component distributions were selected to represent a variety of departures from normality. The three light-tailed distributions with bounded range that were chosen were the uniform distribution on the $0 - 1$ interval ($\beta_2 = 1.8$), the convolution of two such uniform distributions (a triangular distribution with $\beta_2 = 2.4$), and the convolution of three such uniform distributions (a trapezoidal distribution with $\beta_2 = 2.6$). They are subsequently denoted as U1, U2, and U3, respectively.

Five heavy-tailed component distributions were also selected. The first represents the distribution of the product of two mutually independent variables, one having the $0 - 1$ uniform distribution and the other being normally distributed with zero mean and unit variance [i.e., $N(0, 1)$]. This distribution ($\beta_2 = 5.4$) is labeled UN. The second heavy-tailed distribution was chosen to be the Laplace (or double exponential) distribution for which $\beta_2 = 6$. The remaining three heavy-tailed distributions were mixtures of two normal distributions, each with mean zero and variances of 1 and 9, respectively [i.e., $N(0, 1)$ and $N(0, 9)$]. The mixtures were denoted as $(1 - \lambda)\ N(0, 1) + \lambda N(0, 9)$, and the mixing proportions λ were set at 5% ($\beta_2 = 7.653$), 10% ($\beta_2 = 8.333$), and 20% ($\beta_2 = 7.544$).

Simulation Process

A computer program was written to simulate n independent vectors, each having p components drawn independently from the same component distribution. A sample co-

variance matrix S based on these n vectors was then obtained, and the criterion W was derived from S. The appropriate critical value for W was retrieved from tables in Nagarsenker and Pillai (1973). The empirical proportion of Type I errors was obtained by dividing the number of times that W exceeded the given value by the number of data sets simulated. Five thousand replications were made for each combination of n, p, and component distribution to estimate the true Type I error at nominal alpha values of 10%, 5%, 2.5%, and 1%. To check the accuracy of the simulation process, initial computer runs were made using the normal distribution. As may be seen in Table 3, the discrepancies between the empirical Type I errors and their respective true values for the normal case are within 2.3 standard errors for proportions.

Results

Though the simulation was conducted for $p = 2$, 3, 4, and 5, combined with several levels of sample size n, only the data for $p =$ 5 are reported in Table 3. The patterns displayed by the empirical Type I error for $p =$ 2, 3, and 4 are virtually identical to those observed for the case $p = 5$.

The following trends may be deduced from Table 3.

1. The Mauchly W criterion tends to err on the conservative side for light-tailed component distributions, and the discrepancy between the empirical Type I error and nominal alpha is greater for large samples.

2. With heavy-tailed component distributions, the empirical Type I error rates are much larger than the corresponding nominal values. As in the previous case, the differences become more visible as the sample size increases.

3. In all situations under consideration, the ratio of the empirical Type I error to the posted alpha deviates further from unity at smaller alpha values. This trend has also been noticed in most studies regarding the robustness of the F test under nonnormality and/or variance heterogeneity (Collier et al., 1967; Glass, Peckham, & Saunders, 1972; Huynh, 1969).

Discussion of Simulation Study

In the simulation study, the behavior of Mauchly's sphericity criterion W has been documented for a number of nonnormality conditions. For light-tailed distributions, W errs on the conservative side in terms of Type I error. This is partially because W is an increasing function of the variability of the eigenvalues of the sample covariance matrix S. A light-tailed distribution usually is more dense near the mean than is true of a normal distribution. Thus, the eigenvalues calculated from a covariance matrix based on a light-tailed distribution would be expected to display less heterogeneity than those calculated from a covariance matrix based on a normal distribution with the same variance. Hence the critical values under normality for W will be somewhat larger than are appropriate for values of W calculated from light-tailed distributions.

The simulation previously reported clearly indicates that W does not behave badly as long as the component distribution has a tail lighter than that of the normal distribution. Fortunately, most data in the social sciences are obtained from measuring instruments with a limited score range. The corresponding distributions are hence likely to be light-tailed, though probably not as extreme as the uniform distribution. It would be expected that W, along with the normal distribution critical values, should do a reasonable job in terms of Type I error in checking the sphericity assumptions in designs involving repeated measures.

The study also points out the fallibility of the Mauchly criterion in the case of heavy-tailed component distributions. The authors are not aware of a method of overcoming this deficiency, although nonparametric or robust procedures could conceivably be developed. Though W may be relied on in preliminary testing for the validity of the traditional F tests, it may simply be skipped in many instances. In previous articles on approximate tests for repeated measures designs, Huynh and Feldt (1976) and Huynh (1978) have shown that an adjustment in the degrees of freedom would be sufficient to account for most examples of departure of the covariance

Table 3
Empirical Percentages of Type I Error for Mauchly's Sphericity Criterion W Under Selected Situations

matrix from sphericity. If heavy-tailed component distributions are suspected, simply discard the Mauchly sphericity criterion and conduct an approximate test. In most instances the true probability of the Type I error will not be far from the posted nominal alpha. For readers familiar with multivariate analysis, of course, alternative testing procedures such as Hotelling's T and many others based on the union-intersection principle are available (Morrison, 1976).

Conclusions

Details regarding the necessary and sufficient conditions for traditional tests of the within-subject mean square ratios in repeated measures designs are presented in this article. It is shown that these conditions are based on the orthogonal normalized variables associated with each cluster of within-subject mean square ratios based on the same error term. They are far more general than the assumptions of equality of covariance matrices and compound symmetry of the common covariance matrix for all repeated measures. It is shown that appropriate preliminary testing for the mentioned conditions may be carried out within normal distributions via the Box modified likelihood ratio test and the Mauchly sphericity criterion. Both tests are to be conducted on suitably chosen sets of orthonormal variables.

Furthermore, the behavior of the Mauchly criterion for nonnormal data was investigated. It was shown to provide a conservative testing procedure for light-tailed component distributions and to produce more than the nominal percentage of Type I errors for heavy-tailed distributions. Since many nonnormal distributions that occur in the social sciences are light-tailed, the W criterion should be useful for assessing the validity of the application of the traditional tests of repeated measures data.

The other test, the Box test, has also been suspected to be sensitive to nonnormality. Further studies are needed to determine the seriousness of this problem and possibly to identify procedures to overcome it.

Large Sample Variance of Kappa in the Case of Different Sets of Raters

Joseph L. Fleiss
School of Public Health, Columbia University, and Biometrics Research Department, New York State Psychiatric Institute, New York

John C. M. Nee
Biometrics Research Department, New York State Psychiatric Institute, New York

J. Richard Landis
Department of Biostatistics, School of Public Health, University of Michigan

Published formulas for the large sample variance of the kappa statistic that are appropriate for the case of different sets of raters for different subjects, when each set of raters is selected at random from a larger pool of available raters, are determined to be incorrect. New formulas are derived and checked by Monte Carlo simulation. Kappa is shown to be identical, except for terms that go to zero as the number of subjects increases, to the intraclass correlation coefficient resulting from applying a one-way analysis of variance to the data.

Many human endeavors have been cursed with repeated failures before final success is achieved. The scaling of Mount Everest is one example. The discovery of the Northwest Passage is a second. The derivation of a correct standard error for kappa is a third.

Cohen (1960, 1968) presented kappa and weighted kappa as chance-corrected measures of agreement between two raters, each of whom independently classifies each of a sample of subjects into one of k mutually exclusive and exhaustive categories. The standard error formulas that he presented as well as formulas published by Everitt (1968) were shown by Fleiss, Cohen, and Everitt (1969) to be incorrect. The formulas presented in the latter article have been confirmed analytically by Landis and Koch (1977a) and have been confirmed by means of Monte Carlo simulation by Cicchetti and Fleiss (1977) and Fleiss and Cicchetti (1978).

Fleiss (1971) extended kappa to the case in which each of a sample of subjects is rated on a nominal scale by the same number of raters but in which the raters rating one subject are not necessarily the same as those rating another. The standard error formulas presented in that article are incorrect. Landis and Koch (1977b) derived similar statistics for the case of possibly varying numbers of ratings per subject by applying a one-way analysis of variance model to the data. The method they suggested for calculating standard errors yields results appropriate for the nonnull case but overestimates the standard error appropriate for testing the null hypothesis that the parameter is zero.

In this article, formulas for the standard error of kappa in the case of different sets of equal numbers of raters that are valid when the number of subjects is large and the null hypothesis is true are derived. The results of some Monte Carlo simulations confirm that the formulas are correct.

Notation

The notation here is the same as in Fleiss (1971). Let N represent the total number of subjects, n the number of ratings per subject, and k the number of categories into which assignments are made. Let the subscript i, where $i = 1, \ldots, N$, represent the subjects, and the subscript j, where $j = 1, \ldots, k$, represent the categories of the scale.

Requests for reprints should be sent to Joseph L. Fleiss, Division of Biostatistics, Columbia University School of Public Health, 600 West 168th Street, New York, New York 10032.

Define n_{ij} to be the number of raters who assigned the ith subject to the jth category, and define

$$p_j = \frac{1}{Nn} \sum_{i=1}^{N} n_{ij}. \tag{1}$$

The quantity p_j is the proportion of all assignments that were to the jth category. Since $\Sigma_j n_{ij} = n$, $\Sigma_j p_j = 1$.

A motivation of the following formulas, which are simplifications of the expressions presented there, can be found in Fleiss (1971). The measure of the extent of agreement beyond chance in assigning subjects to category j ($j = 1, \ldots, k$) is

$$\kappa_j = 1 - \frac{\sum_i n_{ij}(n - n_{ij})}{Nn(n-1)p_j q_j}, \tag{2}$$

where $q_j = 1 - p_j$. If there is perfect agreement in the assignments to category j (i.e., if each $n_{ij} = 0$ or n), then $\kappa_j = 1$. If, on the other hand, the n_{ij}s vary as binomial random variables with parameters n and p_j, then the expected value of κ_j is 0. The minimum value of κ_j is $-1/(n-1)$.

The overall measure of agreement beyond chance is a weighted average of the κ_js,

$$\kappa = \frac{\sum p_j q_j \kappa_j}{\sum p_j q_j} = 1 - \frac{Nn^2 - \sum \sum n_{ij}^2}{Nn(n-1) \sum p_j q_j}. \tag{3}$$

The overall measure also varies from a minimum of $-1/(n-1)$ for poorer than chance agreement through 0 for just chance agreement to unity for perfect agreement.

Large Sample Standard Errors

The error committed by Fleiss in his 1971 article was to ignore the fact that the denominators of κ and κ_j are subject to the same order of random variation as are their numerators. The results below are derived by taking proper account of the variation in both the numerators and denominators.

It is convenient to define

$$s_j = \frac{1}{Nn} \sum_{i=1}^{N} n_{ij}^2, \tag{4}$$

so that kappa (see Equation 3) may be reexpressed as

$$\kappa = 1 - \frac{n - \sum s_j}{(n-1)(1 - \sum p_j^2)}. \tag{5}$$

Consider the hypothesis that the ratings are purely random in the sense that for each subject, the frequencies $n_{i1}, n_{i2}, \ldots, n_{ik}$ are a set of multinominal frequencies with parameters n and $(P_1, P_2, \ldots, P_k)$, where $\Sigma P_j = 1$. Using known results about moments of powers and products of multinomial variables (the moments given by Fleiss, 1971, in Equations 12–15 are correct, except that the term n_{ij} in Equation 14 should be squared), it may be checked that the covariance matrix Σ of $(p_1, s_1, p_2, s_2, \ldots, p_k, s_k)'$ is given by the following expression:

$$\Sigma = \begin{Vmatrix} \Sigma_{11} & \Sigma_{12} & \cdots & \Sigma_{1k} \\ \Sigma_{21} & \Sigma_{22} & \cdots & \Sigma_{2k} \\ \vdots & \vdots & & \vdots \\ \Sigma_{k1} & \Sigma_{k2} & \cdots & \Sigma_{kk} \end{Vmatrix}, \tag{6}$$

where, letting $Q_j = 1 - P_j$ and

$$F_j = 1 + 2(n-1)P_j, \tag{7}$$

$$\Sigma_{ij} = \frac{-P_i P_j}{Nn} \begin{bmatrix} 1 & F_j \\ F_i & F_i F_j - 2(n-1)P_i P_j \end{bmatrix}, \tag{8}$$

for $i \neq j$, and

$$\Sigma_{jj} = \frac{P_j Q_j}{Nn} \begin{bmatrix} 1 & F_j \\ F_j & F_j + (F_j - 1)Q_j \end{bmatrix}. \tag{9}$$

Under the hypothesis of randomness, the expected value of p_j is P_j, and that of s_j is $P_j[1 + (n-1)P_j]$. The vector $\mathbf{v}$ of partial derivatives of κ with respect to each of its components $(p_1, s_1, \ldots, p_k, s_k)$, evaluated at the parameter values, is

$$\mathbf{v} = \begin{Vmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \\ \vdots \\ \mathbf{v}_k \end{Vmatrix}, \tag{10}$$

where

$$\mathbf{v}_i = \frac{1}{(n-1)\sum P_j Q_j} \begin{bmatrix} -(F_i - 1) \\ 1 \end{bmatrix}. \tag{11}$$

According to standard large sample theory (Rao, 1973), the approximate variance of κ when N is large may be found by replacing

the unknown parameters by their sample estimates in $\mathbf{v}'\Sigma\,\mathbf{v}$. It may be checked by straightforward algebra, then, that the estimated large sample variance of κ is

$$\mathrm{Var}(\kappa) = \frac{2}{Nn(n-1)(\sum p_j q_j)^2} \times [(\sum p_j q_j)^2 - \sum p_j q_j (q_j - p_j)]. \quad (12)$$

The variance of κ_j may be found either by applying the same kind of algebra as above or, more directly, by specializing Equation 12 to the binomial case where $k = 2$ by considering only ratings into or not into category j. In either case, the large sample variance of κ_j is

$$\mathrm{Var}(\kappa_j) = \frac{2}{Nn(n-1)}, \quad (13)$$

independent of the proportions.

For large values of N and under the hypothesis of randomness, κ and the separate κ_js are approximately normally distributed with variances given by Equations 12 and 13. This result follows from the multivariate central limit theorem (Rao, 1973) applied to the average values $\{p_j\}$ and $\{s_j\}$. The kappas are slightly negatively biased, however. This follows from the identity

$$\kappa_j = \frac{\chi^2_j - N}{N(n-1)}, \quad (14)$$

where

$$\chi^2_j = \frac{\sum_{i=1}^{N} (n_{ij} - np_j)^2}{np_j q_j}, \quad (15)$$

the chi-square statistic for testing the homogeneity of N binomial samples. Because the expected value of χ^2_j under the hypothesis is approximately equal to $N - 1$, that of κ_j (and of κ) under the hypothesis is approximately equal to $-1/N(n-1)$.

Thus, when N is large, the statistical significance of κ_j may be tested by referring the quantity

$$z_j = \left[\kappa_j + \frac{1}{N(n-1)}\right]\sqrt{\frac{Nn(n-1)}{2}} \quad (16)$$

to the standard normal distribution. The statistical significance of κ may be tested by referring the quantity

$$z = \left[\kappa + \frac{1}{N(n-1)}\right](\sum p_j q_j) \times \sqrt{\frac{Nn(n-1)}{2[(\sum p_j q_j)^2 - \sum p_j q_j (q_j - p_j)]}} \quad (17)$$

to the standard normal distribution.

The empirical distributions of z and of $\{z_j\}$ were obtained by Monte Carlo simulation for a number of combinations of parameter values. The empirical standard deviations were all close to the theoretical value of unity, and if N is at least 25 or 30, then testing the statistical significance of κ and $\{\kappa_j\}$ by referring the values of z and $\{z_j\}$ to the standard normal distribution seems safe.

The incorrect formulas given in Equations 16 and 23 of Fleiss (1971) overestimate the variance, as do the formulas proposed by Landis and Koch (1977b) for the nonnull case. The use of these formulas, therefore, together with a failure to take account of the negative bias in the kappas, leads to conservative tests of significance.

Kappa As an Approximate Intraclass Correlation Coefficient

Landis and Koch (1977b) approach the problem of measuring the degree of agreement on the jth category by applying the algebra of a one-way analysis of variance to the data resulting from coding assignments to the jth category as 1 and assignments to another category as 0. The mean square within subjects is equal to

$$WMS_j = \frac{1}{Nn(n-1)} \sum_i n_{ij}(n - n_{ij}), \quad (18)$$

and the mean square between subjects is equal to

$$BMS_j = \frac{1}{(N-1)n} \sum_i (n_{ij} - np_j)^2. \quad (19)$$

They take as the measure of agreement on the jth category the sample intraclass correlation coefficient

$$r_{jj} = \frac{BMS_j - WMS_j}{BMS_j + (n-1)WMS_j}, \quad (20)$$

and as the overall measure of agreement a weighted average of these coefficients,

$$\bar{r} = \frac{\sum p_j q_j r_{jj}}{\sum p_j q_j}. \tag{21}$$

It is easily checked that

$$r_{jj} = \frac{1 + \kappa_j(Nn - 1)}{(Nn - n + 1) + \kappa_j(n - 1)}, \tag{22}$$

which is always larger than κ_j. If N is large, however, r_{jj} and κ_j are virtually equal. In fact, if BMS_j is redefined to have N instead of $N - 1$ in its denominator, then r_{jj} and κ_j are identical.

A major contribution by Landis and Koch (1977b) to the measurement of agreement was their consideration of the case of varying numbers of ratings per subject. In addition, they indicated how large sample variances appropriate to the nonnull case could be calculated.

Tests for Homogeneity of Variance in Factorial Designs

Paul A. Games
Pennsylvania State University

Harvey J. Keselman and Jennifer J. Clinch
University of Manitoba, Winnipeg, Canada

The variance portion of Games's three-factor model of inference on independent groups is extended. Six procedures that convert tests of spread into tests of location are reviewed and explored in a Monte Carlo study of how to test variances in a factorial design. The statistic $ln\ s^2$ is shown to be a slight improvement over Overall and Woodward's procedure. The dependence of these two tests on the normality condition is illustrated. Four robust alternatives of somewhat lower power are contrasted. The jackknife test is the most powerful and is only slightly sensitive to leptokurtosis if the ns are equal. The Brown-Forsythe median test is acceptable but it uses average deviations rather than variances. The Box-Scheffé test is always robust. No single test is ideal. A two-stage process is recommended.

Behavioral investigators often attend only to central tendency, even when interesting trends in variability exist in the data. In education, it is desirable to reduce the variance when working with hierarchial tasks. Students will show little divergence on entry behaviors for the next task in the hierarchy, if we have been able to keep the variance small in the first task. Skinner (1958) suggested reduced variances as a desirable consequence from programmed learning, and Block (1973) recognized in his discussions of mastery learning that this outcome was desirable. Unfortunately, most investigators have failed to attend to variances except as a "nasty" assumption with respect to the analysis of variance (ANOVA) on means. Two exceptions to this trend are Birch and Lefford (1967) and Johnson and Baker (1973).

This neglect of variances is probably related to the fact that typical statistics texts teach only the classical omnibus tests on homogeneity of variance that (a) ignore the logical structure of factorial designs and (b) are extremely sensitive (nonrobust) to violations of the normality assumption. The present article presents six tests that can be used in factorial designs of independent groups in a fashion similar to that of the familiar tests on means. Three of the six tests prove to be robust.

Tests Requiring Normality

Overall and Woodward (1974) proposed the Z-variance test, a clever extension and application of the Fisher and Yates (1963) z-score transformation for chi-square statistics. There are problems of clarity in the formulation of the statistic and in the article, however. Given K samples of sizes n_k from independent populations, Overall and Woodward define

$$Z_k = \sqrt{\frac{c_k(n_k - 1)s_k^2}{MS_w}} - \sqrt{c_k(n_k - 1) - 1}, \quad (1)$$

where $c_k = 2 + 1/n_k$ and MS_w is mean square within cells. Overall and Woodward then define

$$F_{(K-1,\infty)} = \sum^{K} Z_k^2/(K - 1). \quad (2)$$

They note that $(K-1)F_{(K-1,\infty)} = \chi^2_{(K-1)}$ and refer to Marascuilo's (1966) statistic $U' = \Sigma[(\hat{\theta}_k - \hat{\theta}_o)^2/\mathrm{var}(\hat{\theta}_k)]$ that is distributed as $\chi^2_{(K-1)}$. $\hat{\theta}_k$ is a normally distributed unbiased estimate of the parameter θ_k, θ_o is the common value of θ_k under the hypothesis of equality,

Requests for reprints should be sent to Paul A. Games, Division of Counseling and Educational Psychology, Pennsylvania State University, 403D Carpenter Building, University Park, Pennsylvania 16802.

and $\hat{\theta}_o$ is an estimate of θ_o. Assuming $\text{var}(Z_k) = 1$ and $\theta_o = 0$, Overall and Woodward derive Equation 2. However, they later recommend, "The z-transformed sample variances can be analyzed by ANOVA for factorial design with one observation per cell" (1974, p. 313). The standard ANOVA will compute deviations squared from the grand mean, in this case, $\bar{Z}$. This procedure is used in their illustrative example, hence they have used a different procedure than in their definition in Equation 2. This problem becomes particularly severe in unequal n factorial designs, in which there are different ways that the row and column marginal means and the grand mean can be defined. Their procedure is analogous to the unweighted means modification of ANOVA. Carlson and Timm (1974) and Applebaum and Cramer (1974) illustrate the complexities of the more desirable least squares analysis of nonorthogonal designs. To avoid these complexities, in the present article we stick with the equal n case.

Bartlett and Kendall (1946) proposed an alternative transformation and illustrated its usage in a two-factor design. They propose using $v_k = ln\, s_k^2$ as the transformed value to compute on each cell and to enter into an ANOVA. (Either $ln\, s^2 = \log_e s^2$ or $\log_{10} s^2$ could be used, since one is a linear transform of the other. The $ln\, s^2$ usage simplifies later results.)

Overall and Woodward (1974) discard this statistic because Bartlett and Kendall "themselves conclude that the ANOVA of log variances is inferior to the more frequently used Bartlett's test (1937) in situations where the two can be compared" (p. 311). However, the inferiority of v_k was demonstrated when equal ns below 12 were used, values of n that were smaller than those used by Overall and Woodward or Levy (1975) in their Monte Carlo studies of Z_k. On such small samples, we also can expect the Z-variance test to be inferior to the traditional one-factor Bartlett test. Unfortunately, neither the Overall and Woodward nor the Levy studies contrasted the two.

On any given set of data, MS_w will be a constant, so the definition can be rewritten as

$$Z_k = \sqrt{\frac{c(n-1)}{MS_w}}\,\sqrt{s_k^2} - \sqrt{c(n-1) - 1} = a\sqrt{s_k^2} - b. \quad (3)$$

Thus Z_k is a linear transform of s_k, the square root of s_k^2. The square root transformation is appropriate for stabilizing the variance of the statistic, if the mean of the statistic is proportional to the variance of the statistic; but the ln transformation is appropriate if the mean is proportional to the standard deviation (Bartlett, 1947). The latter is the case with s^2. $E(s^2) = \sigma^2$, and $\sigma_{s^2} = \sigma^2[(2/n - 1) + (\gamma_2/n)]^{\frac{1}{2}}$, where γ_2 is the kurtosis index of the population. Thus, for the equal n case, use of $v_k = ln\, s_k^2$ will stabilize the variance of the ANOVA entries better than use of Z_k. When H_o is true, and the s_k^2 statistics are reasonably closely clustered, the results of the two transformations will be similar, but as the s_k^2 statistics become more divergent, the difference increases. Thus the effect on power should be greater than the effect on the familywise risk of Type I errors (FWI; Games, 1971).

The disadvantage of both above formulations is that they are exceedingly sensitive to violations of the normality assumption, as are all other classical tests on variances (Box, 1953). Scheffé (1959) shows that $E(v) \approx ln\, \sigma^2$, and $\text{var}(v) \approx (2/(n-1)) + (\gamma_2/n)$. If a good estimate of the common γ_2 is available, it could be used. Box and Anderson (1955) build robust tests for variances by use of an estimate of γ_2. Such estimates require large ns for stability, however, and add great complexity to the computation, while the statistics that Box and Anderson proposed do not readily extend to multifactor cases.

The Scheffé (1959) formulation makes it obvious why the v_k test is so sensitive to nonnormality. By assuming normality, γ_2 is set to 0 to yield $MS_e = 2/(n-1)$. If the populations are platykurtic, then $\gamma_2 < 0$, and this theoretical MS_e is too large, which results in a conservative test. With leptokurtic populations, $\gamma_2 > 0$, so use of the theoretical MS_e results in an excess of Type I errors. Games, Winkler, and Probert (1972) showed that only the latter condition is a problem. Platykurtic populations yield greater power on the classical tests than do normal populations, despite the conservatism at the null hypothesis point. Why object to a reduced risk of Type I error if there is no corresponding power loss?

Tests Robust to Nonnormality

Both Box (1953) and Scheffé (1959) suggest breaking each cell into random subsamples and computing $ln\, s^2$ on each subsample. If each cell has n cases, then I subsamples of m cases each ($n = mI$ when possible) are determined, and values of $v_{ijk} = ln\, s_{ijk}^2$, $i = 1, \ldots I$, are computed in each cell. These values are used as input to an ANOVA with m observations per cell rather than with one observation per cell as in the prior tests. Now MS_w may be computed and is an unbiased estimate of var(v), whether Y is normally distributed or not. This technique has been labeled the Scheffé test (Winer, 1971), the Box-Scheffé test (Levy, 1975), and the Bartlett and Kendall test (Games et al., 1972; Gartside, 1972). We use the Box-Scheffé label here to avoid confusion with the prior Bartlett and Kendall suggestion of using a single value of $ln\, s^2$ per cell.

Games et al. (1972), Games (1975), and Levy (1975) pointed out that the Box-Scheffé test can be used on multifactor designs and is robust to violations of the normality assumption. Levy compared the power of the Overall and Woodward (1974) Z-variance test and the Box-Scheffé test for single-factor designs with equal n and $K = 3$, when Y is normally distributed. Levy concluded, "For all sample sizes, one can plainly see that the Z-variance test is vastly superior to the Box-Scheffé procedure with respect to power" (p. 521). Levy's conclusion is due, however, to an exceptionally poor choice of subsample size for the computation of the Box-Scheffé test. Levy used $m = 2$ for ease of computation in his Monte Carlo study. However, Gartside (1972) and Games et al. demonstrated that the use of subsamples of only two cases produces power far lower than use of intermediate subsample sizes. Martin and Games (Note 1) further investigated the desirable subsample size and concluded that the use of $m \approx (n)^{\frac{1}{2}}$ (or the nearest whole divisor of n, if any) results in optimum power in the Box-Scheffé test. Games et al. report a procedure for a rough estimation of the power of the Box-Scheffé test. When appropriate values of $m = 3$ for $n = 12$, $m = 5$ for $n = 26$, and $m = 6$ for $n = 40$ are used, the estimated powers are uniformly higher than the powers that Levy reports. In the trade-off between robustness and power, the cost of the Box-Scheffé, properly used, is far less than implied by Levy's results or conclusions.

The major disadvantage of the Box-Scheffé test is that the use of random subsamples makes it possible for different data analysts to obtain different outcomes from the same data. This is unlikely with clear-cut data but might be a problem with borderline data. Scheffé (1970) reports that some users randomized and rerandomized until they obtained the results they wanted on a related test using subsample randomization. Brown and Forsythe (1974) rejected the Box-Scheffé test out of hand for this reason.

Fortunately, Brown and Forsythe (1974) reported a robust alternative test for spread that was not subject to the randomization problem. In their procedure, transformed observations are defined as $X_{ijk} = |Y_{ijk} - mdn_{jk}|$, where $i = 1, \ldots n$, and mdn_{jk} is the cell median. Then conventional ANOVA procedures are applied on the X_{ijk}. The Brown and Forsythe technique is more closely related to the average deviation, defined as $AD_{jk} = \Sigma |Y_{ijk} - mdn_{jk}|/n_{jk}$, than to the variance. As such, it should be less influenced by the presence of a few outliers. Unfortunately, derivations of power curves and other properties of the Brown and Forsythe procedure are mathematically intractable.

Another alternative suggested by Brown and Forsythe (1974) is the use of absolute deviations from a trimmed mean, here $X_{ijk}' = |Y_{ijk} - \bar{Y}_{tjk}|$ is used in a conventional ANOVA, where $\bar{Y}_{tjk}$ is the trimmed mean for that cell. This is similar to the Levene (1960) test recommended by Glass (1966), except that Brown and Forsythe use a 10% trimmed mean for which the highest 5% and lowest 5% of the cases are dropped from each sample when computing $\bar{Y}_{tjk}$.

Another alternative is the jackknife test (Miller, 1968), which also subdivides the data into subgroups but has the virtue that all users will obtain the same results, since the subgroups are exhaustive. The subgroups are divided into n subgroups of $n - 1$ observations, that is, one observation is dropped in each subgroup. Then pseudovalues $p_{ijk} = n\, ln\, s_{jk}^2 - (n - 1)\, ln\, s_{ijk}^2$ are defined, where $s_{ijk}^2 =$ the

unbiased sample variance with the ith observation dropped. These pseudovalues are entered into the two-factor ANOVA as the raw data. Prior literature (Brown & Forsythe, 1974; Layard, 1973; Miller, 1968; Martin & Games, Note 1) suggests, however, that on leptokurtic populations, the jackknife test has a Type I error slightly in excess of the nominal alpha. Values of 8%–10% are encountered when $\alpha = .05$.

A virtue of all the present formulations is that they permit multifactor designs, trend tests, or the use of multiple comparisons that are familiar to most ANOVA users. By transforming variance problems into problems of location, they permit a great increase in the type of hypotheses that may be tested (Games, 1978).

Monte Carlo Study

A computer program was written that computed each of the six tests on main and interaction hypotheses on a two-factor independent-groups design. The design was specified as an independent-groups factorial design with four levels of A and three levels of B. The Overall and Woodward (OW) test was formulated using conventional two-factor ANOVA logic, thus taking Z deviations from the observed grand mean rather than assuming $\bar{Z} = 0$, since all the other tests would also be using such conventional ANOVA logic. For each design, 16 samples were drawn for each cell using the pseudorandom number generation "shuffle procedure" of Marsaglia, MacLaren, and Bray (1964). Each such design was replicated 5,000 times, yielding an estimate of FWI or empirical power for $\alpha = .05$ and for $\alpha = .01$. This procedure was repeated using a normally distributed population and also using a population of chi-square values with two degrees of freedom (χ^2_2). The χ^2_2 values were obtained by adding the squares of two independent unit-normal variates.

When the probability of an FWI was assessed, all population variances were set equal to one. For the power comparisons, the variances were specified as in Table 1. In Table 1, the null is false for both main effects, but the null is true for the interaction of the variances. However, due to the use of curvilinear transformations, the interaction null is false for all but the Brown and Forsythe (BF) tests. This is an intrinsic consequence of curvilinear transformations: If additivity is present in the original data, it usually will not be present in the transformed data. Thus the interactions will be excluded when comparing the six tests on power.

Table 1
Values of the Cell Variances (σ_{jk}^2), Row Variances ($\sigma_{.k}^2$), and Column Variances ($\sigma_{j.}^2$) for a Two-Factor Independent-Groups Design

Row factor A_j	Column factor B_k: B_1	B_2	B_3	$\sigma_{.k}^2$
A_1	10	8	6	8
A_2	9	7	5	7
A_3	7	5	3	5
A_4	6	4	2	4
$\sigma_{j.}^2$	8	6	4	

The values obtained for the .05 level of significance and the .01 level of significance showed comparable results, thus only the .05 results are presented in Table 2.

Familywise Risk of Type I Error

The FWI values for the .05 alpha are shown in Table 2. With normally distributed populations, all of the tests show values of FWI that are reasonably close to alpha. The Bartlett and Kendall (BK) and Brown and Forsythe absolute deviation from the trimmed mean (BF_M) yield FWIs slightly larger than alpha, with mean FWI values of .064 and .057, respectively. The jackknife (JK) and Brown and Forsythe absolute deviation from the median (BF_{mdn}) are slightly conservative with mean FWI values of .042 and .036, respectively.

Under the χ^2_2 distribution, the BK and OW tests show the expected extreme FWI values over .05. The BF_M test also shows an inflated FWI approximately three times α, whereas the JK again shows a slight inflation to an FWI $\approx$ .089. Only the Box-Scheffé (BS) and BF_{mdn} tests show excellent control of FWI when the populations are leptokurtic and skewed.

Power

Since all the tests show reasonable control of FWI when the populations are normally

	.064	.052	.042	.057	.036	.047	.540	.520	.089	.158	.046	.052

Note. BK = Bartlett and Kendall; BS = Box-Scheffé; BF_M = Brown and Forsythe absolute deviation from the trimmed mean; BF_{mdn} = Brown and Forsythe absolute deviation from the median; JK = Jackknife; OW = Overall and Woodward. When $n_{jk} = 16$, the subsample size for the BS test was 4, and the BF_M test used a 12.5% trimmed mean. When $n_{jk} = 25$, the subsample size for the BS test was 5, and the BF_M test used an 8.0% trimmed mean. For all probabilities, $\alpha = .05$.
* $p < .05$ for deviation from the expected familywise risk of Type I error.

distributed, all can be compared for power. As expected, the two tests based on classical theory, the BK and OW, are more powerful than any of the more robust tests. As predicted the BK is always more powerful than the OW. Of the two tests that always provide good control of FWI, the BF_{mdn} is always more powerful than the BS.

Under the χ^2_2 populations, only tests that provide reasonable control of FWI are included. Although the JK is of borderline status in that FWI was slightly inflated, which inflates power also, it was included in Table 3 for comparison to the BS and BF_{mdn}. The power differences between the three tests are relatively small, with the largest difference only .065.

Discussion

If the experimenter is confident that the underlying data are normally distributed, any of the six tests covered could be considered adequate in terms of practical control of FWI. The choice between tests would then be based on power. The tests (under the Normal distribution) are listed from the most powerful to the least powerful (from left to right, respectively) in Tables 2 and 3. There is a gradual reduction as you go from left to right in each row, though many adjacent differences are certainly not significant. Thus, if the experimenter is confident of normality, the BK test is best, although the difference between the BK and the OW test is not large.

However, the experimenter often has little grounds for confidence in the shape of the underlying distributions, particularly with small to medium *n*s. If the populations are leptokurtic, the BK and OW tests can have absurdly large FWI values that far exceed the nominal alpha. Similarly, this study has confirmed Brown and Forsythe's (1974) finding that their BD_M test is not robust when skewed populations are encountered. Only three tests remain relatively robust under all forms of populations studied to date. Of these, the JK is the most powerful, but it is accompanied by a slight rise in FWI under leptokurtosis, sometimes reaching an FWI as large as two alpha. The BF_{mdn} test is next in power but has the disadvantage that it is a test of average deviations rather than variances, and Fellers (Note 2) suggests that it is erratic for *n*s as

Table 3
Empirical Power Probabilities for a Two-Factor Independent-Groups Design

Sample size	Normal, N (0, 1) BK	OW	JK	BF_M	BF_{mdn}	BS	Skewed leptokurtic, χ^2_2 JK	BF_{mdn}	BS
$n_{jk} = 16$									
A	.672	.590	.546	.538	.441	.378	.281	.237	.216
B	.755	.686	.656	.642	.562	.483	.307	.291	.259
$n_{jk} = 25$									
A	.874	.818	.817	.756	.694	.649	.366	.368	.330
B	.938	.898	.910	.852	.817	.756	.429	.465	.418

Note. KB = Bartlett and Kendall; BS = Box-Scheffé; BF_M = Brown and Forsythe absolute deviation from the trimmed mean; BF_{mdn} = Brown and Forsythe absolute deviation from the median; JK = jackknife; OW = Overall and Woodward. When $n_{jk} = 16$, the subsample size for the BS test was 4, and the BF_M test used a 12.5% trimmed mean. When $n_{jk} = 25$, the subsample size for the BS test was 5, and the BF_M test used an 8.0% trimmed mean. For all probabilities, $\alpha = .05$.

small as 5. The BS test deals more directly with variances as such and always has an FWI $\approx \alpha$, but it is lowest in power and has the disadvantage that different random subsamples might yield different outcomes.

Thus there is no one test that can be universally recommended without qualification. O'Brien (1978, in press) gives reasons why the power relations of the several tests vary with the kurtosis of the populations. O'Brien recommends the BF_{mdn} test and the use of the JK on s^2 directly (rather than on $ln\ s^2$ as in the present study). The authors note that platykurtosis is rare in the behavioral data we have seen, since skewed and/or leptokurtic data is more common. If the experimenter is reasonably confident that the data are not platykurtic, the minimal computations needed for the BK test are a reasonable first step.

If this test is not significant, the null hypothesis is retained. However, if the BK is significant, there is the possibility that the result is a Type I error due to leptokurtosis in the population. Thus it is desirable to also reject the null hypothesis by one of the robust tests before making strong interpretations about heterogeneous spread. This two-step process is not ideal, but neither are any of the tests investigated to date.[1]

The Role of Fear in Theories of Avoidance Learning, Flooding, and Extinction

Susan Mineka
University of Wisconsin—Madison

The course of fear conditioning and extinction in the avoidance-learning context is complex. This article summarizes the major lines of evidence that demonstrate a dissociation or desynchrony between measures of fear and avoidance responding. The evidence bearing on the role of fear in theories of avoidance learning and extinction is reviewed and critically evaluated. In addition, research is discussed regarding the determinants of fear over the course of avoidance acquisition, flooding, and extinction. Particular emphasis is placed on discussing the extent to which fear extinction is necessary and/or sufficient for avoidance response extinction both with conventional extinction procedures and with response prevention techniques.

In animals and humans fear has long been assumed to play an important role in the mediation of avoidance behaviors that in turn have often been assumed to underlie a variety of neurotic behaviors. The avoidance behavior that frequently accompanies a state of fear has actually been considered by some theorists to be one of the response systems inherent in our definition of fear itself. Lang (1968, 1971), for example, has argued that fear is a complex construct that in humans includes at least three different response systems—verbal/cognitive (subjective), motor (behavioral avoidance), and psychophysiological. These three response systems do not always covary together, and treatments designed to reduce so-called fear may, at least initially, affect one system but not the others. (See also Hodgson & Rachman, 1974; Rachman & Hodgson, 1974.)

Other theorists, whose primary interest has been avoidance behavior in infrahuman organisms, have attempted to understand the role that fear plays in mediating the acquisition, maintenance, and extinction of learned avoidance responses. Over the past 15 years or so, it has become increasingly apparent that the role of fear in mediating any of these facets of learned avoidance behavior is at best not a simple one. In particular, there is often a marked dissociation between fear and avoidance responding (Riccio & Silvestri, 1973) that has led a number of theorists to question whether fear plays any role at all in mediating avoidance responding (e.g., Herrnstein, 1969; Hineline, 1977).

This article has three goals. First, after a discussion of the measurement of fear in animals, there is a brief review of the evidence on dissociation or desynchrony between fear and learned avoidance behavior. Given this background, the second goal is to evaluate comprehensively and critically the role that fear plays in various theories of avoidance acquisition, maintenance, and extinction. Because the majority of the work in this area has centered on the question of the role that fear extinction plays in mediating avoidance response extinction through response prevention or flooding techniques, particular emphasis is placed on work in that area. The third goal of this article is to review, where pertinent evidence is avail-

able, what determines the course of fear acquisition and extinction in avoidance-learning contexts. In particular, attention is focused on how the avoidance context influences the dynamics of fear conditioning and extinction.

Measurement of Fear

Conditioned fear emerges as the result of pairing a neutral stimulus with an aversive or noxious unconditioned stimulus. Over the past 50 years, numerous response systems have been shown to be sensitive to the effects of aversive conditioning procedures: defecation, heart rate, suppression of ongoing consummatory or operant appetitive behavior, learning a response to escape from a fearful stimulus, passive avoidance of a fearful stimulus, facilitation of ongoing operant avoidance behavior, and so forth. Each one of these indices of conditioned fear has been more or less extensively validated by determining whether the degree of fear as measured by that index is sensitive to conditioning parameters that would be expected on some a priori basis to affect the level of fear that is conditioned (e.g., intensity of the aversive stimulus, number of conditioned stimulus – unconditioned stimulus [CS–US] pairings, etc.). These validation procedures have, of course, each assumed that there is some degree of correlation between the magnitude of the observable response and the internal state of fear itself (McAllister & McAllister, 1971).

Experiments in the area of fear and avoidance have tended to use one of four of the indices of conditioned fear mentioned previously. Probably the most widely used index of the results of an aversive conditioning procedure has been the conditioned emotional response (CER) index, first developed by Estes and Skinner (1941). They observed that hungry rats trained to barpress for food reinforcement decreased their rate of responding when a warning signal was presented for an impending aversive event (usually electric shock). Estes and Skinner labeled this pattern of suppression of ongoing operant appetitive behavior "conditioned anxiety," and over the past 35 years, this phenomenon has been shown in numerous studies to be a reliable and sensitive index of aversive conditioning in a variety of different species (Davis, 1968). The term "conditioned emotional response" was first used by Hunt and Brady (1951) to describe this phenomenon, and it is now the term most widely used to describe this index of conditioned fear or anxiety, two terms that are most often used interchangeably by experimental psychologists. Although others have used the term CER in a more general way to describe the state that has presumably been conditioned in an aversive conditioning procedure, no matter how it is being measured (e.g., heart rate, suppression of operant appetitive behavior, facilitation of avoidance behavior, etc.), in this article the term will be used only to refer to this one particular index of conditioned fear, that is, suppression of operant appetitive behavior. It should be emphasized that in spite of the wide use of the CER as an index of fear or aversive conditioning, there is as yet no consensus as to why positively reinforced behavior is suppressed during a stimulus paired with an aversive stimulus such as shock. (See Blackman, 1977, for one current discussion of this topic.)

A second and closely related index of aversive conditioning used in some of the more recent experiments described later is that developed by Sidman, Herrnstein, and Conrad (1957), Herrnstein and Sidman (1958), and Rescorla and LoLordo (1965). These investigators found that when stimuli paired with shock were presented to monkeys or dogs who were responding on a Sidman (unsignaled) avoidance baseline, the rate of avoidance responding increased dramatically for the duration of the warning stimulus. This facilitation or energization of an operant maintained by negative reinforcement has subsequently been used extensively as an index of conditioned excitatory and inhibitory states based on aversive reinforcers (e.g., Rescorla & Solomon, 1967; Weisman & Litner, 1969, 1972). Scobie (1972) and Morris (1974) have even suggested that it may be a more sensitive index of fear or aversive conditioning than the CER because it can sometimes detect evidence of conditioning when the CER does not.

It should be noted here that the same warning stimulus can be used to produce either suppression or facilitation of ongoing operant behavior, depending on whether that operant is maintained by positive or negative reinforcement. For example, Sidman (1958) reported that monkeys that were maintained on a concurrent chain-pulling response for food reinforcement and lever-press response for shock avoidance showed suppression of the chain-pull response and facilitation of the lever-press response during a warning stimulus for shock. Such results present one of the strongest lines of evidence that there is indeed some central mediating state that is being conditioned in an aversive conditioning procedure. Out of convenience, many experimental psychologists have chosen to use the word *fear* to describe that state, which may manifest itself through a facilitation or suppression of ongoing behavior (Rescorla & Solomon, 1967). In addition, such results underscore the point that it cannot be suppression or facilitation per se that is being conditioned in such experiments; rather, it seems that some central state is being conditioned, the motivating properties of which manifest themselves differently according to which other motivating state is maintaining the operant behavior.

A third index of fear used in some of the experiments reported later is the passive avoidance of a place in which aversive conditioning trials have previously occurred. When given a choice, animals will tend to avoid any such stimulus or place previously paired with an aversive stimulus. To maximize the incentive to approach a fearful place, animals are often food deprived prior to the test, and their latency to enter and eat in the fearful place is measured. The fourth and final index of fear used by some investigators in this area is the conditioned heart rate response. There appears to be some variability between species in the nature of this response, since rats tend to show heart rate decreases, whereas dogs and monkeys tend to show heart rate increases (Brady & Harris, 1977).

Early observations that there is often a lack of concomitance among these different results of an aversive conditioning procedure date back at least as far as Gantt's (1937, 1953) results which indicated that different components of a response conditioned with shock as the US develop at different rates and persist for different periods of time, and the result is a disharmony or cleavage in behavioral, somatic, and psychophysiological response systems. Gantt used the term schizokinesis to describe this phenomenon that he studied most extensively in dogs. More recently, similar observations have been made in several other species. For example, DeToledo and Black (1966) and Brady, Kelly, and Plumlee (1969) have reported that in an aversive conditioning procedure, rats and monkeys show more rapid acquisition of suppression of operant appetitive behavior (CER) than of a heart rate conditioned response. Together, such results indicate that the search for any one uniquely valid index of fear or aversive conditioning in animals will be futile, just as recent evidence from humans has suggested it should be (e.g., Lang, 1968).

This brief review of the measurement of fear in animals certainly indicates that the task of those interested in the relationship between fear and avoidance responding is not an easy one. Given the wide range of measures that may be sensitive to the effects of an aversive conditioning procedure, theorists interested in this relationship should ideally have at hand data that uses multiple-response measurements. Certainly, results that emerge using one index of fear cannot be assumed to apply if a different index of fear is being used. Unfortunately, however, most investigators in this area have used only one index response at a time in their attempts to understand the role of fear in avoidance behavior. Nevertheless, numerous interesting results have emerged over the past 20 years that do help us understand the extent to which fear[1] does or does not play a role in avoidance-learning contexts. More generally, we will see that even when the role

[1] The term *fear* will be used in the present article to refer to any of the four patterns of results of aversive conditioning procedures that have been described previously.

of fear in mediating avoidance responding is in doubt, the question of what happens to fear over the course of avoidance acquisition, maintenance, and extinction is still an interesting and important one. All the conditions necessary for the acquisition and extinction of fear are automatically present in the avoidance-learning context, and yet the CS–US contingency in this aversive conditioning context is unusual, that is, it is a partial reinforcement schedule with nonreinforced CS events whose abbreviated and varying durations are determined by the avoidance latency of the subject. As is demonstrated, the dynamics of fear conditioning and extinction in this unusual context are more complex than those traditionally seen in more straightforward Pavlovian fear conditioning paradigms.

Dissociation Between Fear and Learned Avoidance Behavior

Interest in the association between fear and avoidance responding probably stems from the early appeal of Mowrer's (1947) two-process theory that ascribes a major role to fear as a motivational state in the acquisition of learned avoidance responses. According to this theory, fear, which is conditioned on early trials of a signalized avoidance procedure, serves to motivate the learning of a response that serves to reduce the fear. Reinforcement for avoidance responding comes from termination of the fear-evoking CS. In this theory fear is necessary to motivate the response; once fear has disappeared or extinguished, the avoidance operant should also extinguish. And given a traditional extinction procedure in which shock is no longer presented, fear extinction should be both necessary and sufficient for avoidance response extinction. Other two-process theorists such as Schoenfeld (1950), Sidman (1953), and Dinsmoor (1954) have not invoked the motivational concept of fear in their theories but rather have maintained that stimuli paired with shock early in avoidance become noxious or aversive; consequently, their removal is reinforcing and the avoidance operant is learned. Although these theorists do not use the motivational concept of fear, the aversive or noxious quality of the stimuli whose removal provides reinforcement for the avoidance response should extinguish according to the laws of classical conditioning. Hence the same basic predictions follow from these theories as from Mowrer's theory regarding the necessary and sufficient conditions for avoidance response extinction.

The relationship between fear and avoidance responding is considerably more complex than these early two-process theories predicted. First, there is now considerable evidence that fear of the CS, as indexed by the CER, becomes attenuated over the course of avoidance learning. Kamin, Brimer, and Black (1963) and Starr and Mineka (1977) found that rats trained to a criterion of 27 consecutive avoidance responses (CARs) showed less suppression during the CS than those trained to a criterion of only 9 CARs. Mineka and Gino (Note 1) have further shown that this attenuation of the CER does not occur because the avoidance response itself is about to extinguish. Animals trained to a criterion of 27 CARs show approximately the same resistance to extinction as do animals trained to only 9 CARs. So fear of the CS, as indexed by the CER, is clearly not monotonically associated with the strength of an avoidance response, although it should be noted that no one has yet demonstrated avoidance responding in the complete absence of fear of the CS. Using a different index of fear or stress, Brady (1965) also reported a dissociation between avoidance performance and a physiological correlate of the CER—increases in plasma 17-hydroxycorticosteroid (17-OH-CS) levels. Brady's monkeys showed progressive elevation of 17-OH-CS levels over the first 72 hours of avoidance training, which was then followed by declining levels of 17-OH-CS over the succeeding weeks of avoidance training (Brady & Harris, 1977). Similarly, Coover, Ursin, and Levine (1973) reported that plasma-corticosterone levels in rats were considerably elevated following early avoidance training sessions but that after many (17) training sessions, when avoidance performance was asymptotic, plasma-corticosterone levels only showed small increases over basal levels.

In a somewhat different vein, Rachlin and Herrnstein (1969) have reported a dissociation between the suppressive effects of an aversive shock and its capacity to sustain avoidance. In their second experiment, they found that pigeons who showed little suppression of keypecking with noncontingent shock (CER procedure) did show pronounced negative choice (avoidance) for that component of the schedule. At a minimum, these results suggest that the rate of responding (essentially the CER index of fear) during a stimulus signaling noncontingent shock is not well correlated with the capacity of that stimulus to sustain avoidance. Such results certainly present a dilemma to theorists who maintain that there is any kind of simple relationship between the capacity of a stimulus to sustain avoidance and its capacity to suppress operant appetitive responding.

A second prediction of two-process theory regarding fear and the extinction of avoidance responding has also not been substantiated. In particular, fear extinction does not appear to be necessary for the extinction of the avoidance operant. Although Black (1959) did find that the heart rate conditioned response (CR) extinguished considerably more rapidly than the avoidance response in dogs, he found no significant correlation between the speed of extinction of the cardiac CR and the avoidance response. Using the CER rather than heart rate as an index of fear, Kamin et al. (1963), by contrast, found evidence of avoidance response extinction in the absence of much fear extinction. Rats that were extinguished to a moderate criterion (5 consecutive failures to respond) were still quite fearful of the CS as indexed by the CER, and animals that were extinguished to a more stringent criterion (20 consecutive failures to respond) still showed nonzero levels of fear. Other investigators who used flooding or response prevention techniques to hasten rapid extinction of an avoidance response have reached similar conclusions regarding the lack of necessity of fear extinction in producing avoidance extinction. Coulter, Riccio, and Page (1969), for example, have shown that animals whose avoidance response has been extinguished following flooding are more fearful than animals extinguished with a conventional extinction procedure. In addition, Mineka and Gino (1979a) have shown that an amount of response prevention sufficient to hasten avoidance response extinction does not reduce fear of the CS. So with flooding, as with conventional extinction procedures, fear extinction is not necessary for extinction of the avoidance operant.

This brief summary highlights the evidence showing dissociation between fear and learned avoidance behavior (see also Hodgson & Rachman, 1974; Rachman, 1976; Rachman & Hodgson, 1974; Riccio & Silvestri, 1973). Considerably more discussion and elaboration of this evidence, as well as of the determinants of this dissociation, is made in the remainder of the article. We now turn to a discussion of the role of fear in various theories of avoidance acquisition and maintenance. Attention is focused on how some of these theories have evolved to handle this evidence on dissociation between fear and avoidance.

Fear in Avoidance Acquisition and Maintenance

The Role of Fear in Various Theories of Avoidance Learning

Of all the theories discussed here, Mowrer's (1947) two-process theory clearly ascribes the most important role to fear at various stages of avoidance acquisition, maintenance, and extinction. This theory may, in fact, provide a plausible account for how an avoidance response is initially learned, but it is the phenomenon of the persistence of learned avoidance responses that has most intrigued and plagued learning theorists for the past 25 years. And so, although two-process theory in its various forms has dominated both the theorizing and the experiments done in the field of avoidance learning, its most serious shortcomings have consistently been in its inability to explain satisfactorily the high resistance to extinction of well-learned avoidance responses (e.g., Solomon, Kamin, & Wynne, 1953). The dilemma for two-process theory is that

after dozens or hundreds of consecutive avoidance responses, the source of reinforcement for responding is no longer apparent because each successful avoidance trial constitutes a Pavlovian extinction trial. Hence the fear CR should gradually extinguish, thus removing CS termination as a possible source of reinforcement. After that, the avoidance operant should proceed to extinguish. But as we have already seen, even when the fear CR does become attenuated, the avoidance operant does not immediately begin to extinguish (Kamin et al., 1963; Starr & Mineka, 1977; Mineka & Gino, Note 1).

Solomon and Wynne (1954) attempted to rescue two-process theory from this dilemma by adding to it the two principles of anxiety conservation and the partial irreversibility of the conditioned fear response learned with traumatic shock. These two principles have not proved very useful, however, in explaining the results of experiments demonstrating high resistance to extinction of avoidance responses learned with only moderate levels of shock (Brush, 1957) and conversely the relatively rapid extinction of the CER, even with traumatic shock (Annau & Kamin, 1961). Rescorla and Solomon (1967) further revised two-process theory to account for the apparent lack of fear in the well-trained animal (e.g., Kamin et al., 1963). They postulated that fear is a central state and therefore that lack of concomitance between peripheral measures of fear and avoidance responding does not constitute evidence against two-process theory. This central state of fear, however, is subject to the normal laws of Pavlovian conditioning, including extinction. Thus it is still unclear why this central state of fear does not extinguish in the well-trained animal, and if it does, where the motivation and reinforcement for continued responding come from.

Konorski (1948) and Soltysik (1963) attempted to explain why the fear CR should not extinguish by postulating that it is protected from extinction by the avoidance response that becomes a CS− for shock (inhibitory CS predicting no shock). One problem with this explanation is that it is based on protection-from-extinction experiments done with appetitive responses; no one has demonstrated protection from extinction when the CS− follows the CS+, as in the avoidance case (see LoLordo & Rescorla, 1966; Seligman & Johnston, 1973). Furthermore, the theory explains why fear should persist and provide motivation for responding. However, the evidence discussed previously (e.g., Kamin et al., 1963; Starr & Mineka, 1977) suggests that fear attenuates over the course of avoidance training.

The more recent safety signal or positive reinforcement revision of two-process theory also assumes that the avoidance response becomes a CS− for shock (Bolles, 1970; Weisman & Litner, 1969, 1972). However, this theory does not require that the CS− protect the CS+ from extinction because the CS− assumes the role of a positive reinforcer. The animal continues to make avoidance responses because the response itself (CS−) becomes a positive reinforcer, and fear is not necessary for continued motivation of the avoidance response once the response has become a good CS−. The chief problem with this explanation is that no one has demonstrated that a CS− continues to be a positive reinforcer when it is no longer presented in a fear-eliciting situation (Grossen, 1971; LoLordo, 1969; Seligman & Johnston, 1973). Thus the safety-signal account must posit that the CS+ was protected from extinction to account for the maintenance of the avoidance response as a positive reinforcer (CS−). Until independent evidence exists that residual fear of the CS+ or of the situational cues remains during asymptotic avoidance when the CS− is a positive reinforcer, the safety signal account of the extreme persistence of avoidance responding in extinction is incomplete.

Other theorists (e.g., D'Amato, 1970; Herrnstein, 1969; Hineline, 1977) have further de-emphasized the role of fear in avoidance learning and have instead emphasized the CS's role as a discriminative cue, which "sets the occasion" for responding. The response is presumed to be reinforced by a reduction in shock frequency rather than by reduction of fear. One of these theorists' strongest lines of evidence against the role of the CS as the motivational mediator of an avoidance response comes from the results of

several experiments that attempted to determine if an animal could learn to avoid a CS or discriminative stimulus (S^D) for an avoidance response. For example, Sidman (1955) pretrained cats and rats on an unsignaled shock-delay procedure and then introduced a 5-sec preshock cue that could be delayed or removed. He found that most of the responses occurred during the cue and that the 25%–30% of the responses that did occur in the absence of the cue mostly occurred in postshock bursts. These results suggest that although the removal of a cue can maintain responding, its delay apparently cannot. From the traditional two-process standpoint, one might expect that the animals would learn to avoid a conditioned aversive stimulus if its removal acts as a reinforcer, and yet this does not appear to happen. These results and others summarized by Hineline strongly suggest that the CS in a discriminative avoidance procedure "cannot be seen as simply providing a classically conditioned surrogate for the shock, for several effects are independent of its relation to shock" (p. 396). These theorists do not deny that Pavlovian conditioning of fear may go on in avoidance training and may even affect the rate of responding (Rachlin & Herrnstein, 1969, p. 90), but they do strongly assert that such "classically conditioned responses are not a requirement for the instrumental behavior" (Herrnstein, 1969, p. 61). These theories are, therefore, relatively uninterested in what happens to fear over the course of avoidance learning, although they would probably maintain that the determinants of any fear that does exist should be the result of no more than just the Pavlovian contingencies inherent in the procedure.

Seligman and Johnston (1973) have recently proposed a cognitive theory of avoidance learning that ascribes a role to fear only in the initial stage of training. In the early phase of learning, fear is conditioned to the CS and may be involved in the elicitation of responses. Gradually, however, two expectancies are acquired that serve to maintain the response: an expectancy that a response will be followed by no shock and an expectancy that no response will be followed by shock. If no shock is assumed to be preferred to shock, these two expectancies are sufficient to maintain responding even after fear has extinguished. This theory then predicts that fear and avoidance behavior will not always be well correlated. It further assumes that the degree of residual fear at any phase will be a function of how many Pavlovian fear extinction trials have occurred as a result of successful avoidance responses.

The Determinants of Fear Over the Course of Avoidance Learning

These newer theories of avoidance learning were developed partially as a result of the inability of two-process theory to explain satisfactorily the dissociation or desynchrony between fear and avoidance responding. Each of these theories postulates some new mechanism other than fear to explain the persistence of avoidance responses, for example, the discriminative role of the CS in setting the occasion for a response that results in a reduction of shock frequency or the role of response-outcome expectancies in motivating responses that produce preferable outcomes (i.e., no shock). An explanation of why there is a marked dissociation between fear and avoidance behavior has received only cursory attention (e.g., Seligman & Johnston's, 1973, assumption that fear extinguishes as a result of a simple Pavlovian fear extinction process). However, even if fear does not play a central mediating role in avoidance, the avoidance training procedure automatically programs the necessary and sufficient conditions for the Pavlovian conditioning of fear. Therefore, the question of what happens to that fear over the course of avoidance maintenance and extinction remains one of enormous practical and theoretical importance at least for those interested in fear, even if not for those interested in avoidance.

In a preliminary attempt to study the determinants of fear over the course of avoidance learning, Starr and Mineka (1977) tested the hypothesis that attenuation of fear over the course of avoidance learning results from Pavlovian fear extinction. In a replication and extension of Kamin et al.'s (1963) widely cited study that used the CER as an index of fear, Starr and Mineka compared

fear of the CS in rats trained to 3, 9, or 27 CARs (avoidance-learning [AL] groups) with that of their strictly yoked partners (yoked avoidance-learning [YAL] groups), who received the same pattern of CS and US events but had no avoidance response available. The usual attenuation of fear occurred in the well-trained animals. (The AL-27 group showed less suppression than the less well-trained animals—the AL-3 and AL-9 groups.) However, the yoked group (YAL-27), which had received the same Pavlovian sequence of CSs and USs as the AL-27 group, did not show attenuation of fear. These results suggest that the response contingency per se contributes to the fear attenuation that occurs in well-trained animals.

That a simple Pavlovian fear extinction account does not sufficiently explain attenuation of fear is further supported by other results of Starr and Mineka's (1977) first experiment. Comparisons were made with a third set of groups that were yoked only for the excitatory Pavlovian trials that occurred during the course of avoidance training. These yoked fear conditioning (YFC) groups received the same number and pattern of CS–US pairings as did their AL masters, but they received no nonreinforced CSs. None of the YFC groups differed from each other or from any of the YAL groups. The YFC-27 group did, however, show more fear than the AL-27 group. Because the YFC-27 and YAL-27 groups did not differ in fear, whereas the YFC-27 and AL-27 groups did, simple Pavlovian fear extinction cannot account for the attenuation of fear observed in the AL-27 group. The lack of difference between the YAL-27 and YFC-27 groups is particularly striking in light of the fact that the YAL-27 (and AL-27) group had an average of 63% nonreinforced CS trials, whereas the YFC-27 group had only had reinforced CSs.

To determine which aspect of the response contingency accounts for the decline in fear observed in the AL-27 group, Starr and Mineka (1977) performed a second experiment to assess the role of feedback from avoidance responses in producing this attenuation. One group of animals was trained to a criterion of 36 CARs in a paradigm in which each response was followed by an exteroceptive feedback signal (AL-36-FS). A second group of animals was strictly yoked to the AL group (YAL-36-FS), that is, they did not have an avoidance response available, but they did have a feedback stimulus mimicking the response of the AL group. A third group was also yoked to the AL-36-FS group except that they received no feedback signal (YAL-36-NFS). Both groups (AL-36-FS and YAL-36-FS) that received feedback displayed less fear as indexed by the CER than did the group that received no feedback (YAL-36-NFS), so the response contingency per se is not necessary for the attenuation of fear. The feedback from the avoidance response is sufficient to produce the attenuation.

The mechanism through which feedback produces this attenuation of the CER is not clear. One possibility is that less fear is conditioned to the CS when an FS is present (either in the form of an avoidance response, or an exteroceptive signal). This could occur if an FS were to functionally reduce the intensity of the US by partially inhibiting the fear reaction that would otherwise persist for several seconds following US termination. A second mechanism that might account for the role played by feedback in the attenuation of fear is that fear may extinguish faster when an FS is present. An FS that becomes a powerful conditioned inhibitor of fear may reduce the overall level of fear (e.g., Seligman, 1968). Extinction of fear of a CS presented against such a background might proceed at a faster rate. Although there is as yet no direct evidence bearing on this possibility, it is contrary to the predictions of the Rescorla-Wagner (Rescorla & Wagner, 1972) model that assumes stimuli compete for inhibitory strength. If powerful inhibitory stimuli are already present, this should reduce the amount of inhibitory strength that can accrue to a CS on any extinction trial, so groups with feedback should show less extinction of fear of the CS than groups without feedback. At present, the viability of either of these mechanisms for explaining the role of feedback in producing an attenuation of fear remains to be determined.

Other investigators have also observed attenuation of fear over the course of avoidance learning (e.g., Linden, 1969; Weisman & Litner, 1972), but this is not a universal result. Morris (1974) observed no attenuation of fear in rats trained to 27 CARs when he used a transfer of control test on a Sidman avoidance baseline (Rescorla & LoLordo, 1965); that is, the 27 group showed facilitation of avoidance during the CS equal to that of the 9 group. Morris used an FS following avoidance responses, and this may account for his failure to observe attenuation because attenuation may already have occurred in his AL-9 groups that received an exteroceptive FS, or as discussed earlier, less fear may be conditioned in the first place when an FS is present. Alternatively, different results may be obtained in animals tested for fear with the CER as opposed to the Sidman procedure. The weight of evidence indicates that fear does attenuate with extended avoidance training, although which mechanism produces this attenuation is not yet clear. It should again be noted, however, that fear has never been demonstrated to extinguish completely (e.g., by a CER test or with the Sidman procedure) even with extensive training.

That fear diminishes over the course of a run of consecutive avoidance responses would not be particularly surprising even to a two-process theorist, if the avoidance response concurrently became weaker. If this were the case, one would not be so inclined to speak of a dissociation between fear and avoidance. Recent results of Mineka and Gino (Note 1), however, indicate that the avoidance response is not weaker after a run of 27 consecutive responses than after a run of only 9 responses. Animals trained to a criterion of 27 CARs, in a situation comparable to that of Starr and Mineka (1977), are equally resistant to extinction as animals trained to a criterion of 9 CARs. As indicated by Mackintosh (1974, p. 334), this result creates a serious theoretical problem for theorists who argue that fear motivates the responding of a well-trained animal. By contrast, these results do not present a problem for other theorists who postulate other sources of motivation or reinforcement for avoidance.

Fear and the Extinction of Avoidance Responses

The Role of Fear Extinction in Traditional Avoidance Extinction

The dissociation between fear and avoidance behavior discussed so far has been the diminution of fear as the avoidance response becomes better learned. A two-process theorist might assume that fear would ultimately diminish to a sufficient extent to cause extinction of the avoidance response. As demonstrated earlier, the traditional two-process theory of avoidance in fact assumes that fear extinction precedes and determines avoidance response extinction, but this simple analysis is not correct: The direction of the dissociation between fear and avoidance behavior is not always the same. Rather, as extinction of the avoidance response begins, fear of the CS remains fairly intense. Kamin et al. (1963) reported that animals at a moderate extinction criterion (five consecutive failures to respond) were nearly as fearful of the CS as indexed by the CER as animals that had received no extinction trials. Clearly, animals who have reached a moderate avoidance extinction criterion have not done so because their fear has extinguished. Animals must begin to stop responding for some reason other than that their fear has extinguished. As extinction of the response proceeds, fear extinction is likely to follow. Unfortunately no single experiment has compared fear attenuation (and extinction) across the course of the acquisition of a well-trained avoidance response and its extinction. It is possible that fear may temporarily increase when the animal begins to cease responding. This possibility is suggested by a comparison of the results of Kamin et al.'s two experiments, which unfortunately are not strictly comparable because of differential delay of the time when the CER test was made. Kamin et al.'s animals who had made five consecutive nonresponses (failures to respond in the CS–US interval) were more afraid of the CS than

were the animals who had made 27 consecutive responses.

This dissociation between fear and avoidance responding during extinction is nowhere more apparent than in the literature on the flooding of avoidance responses. Flooding or response prevention techniques are effective in producing rapid extinction of well-learned avoidance responses, even though such responses are resistant to extinction with conventional extinction procedures. These techniques involve prolonged exposure to the CS, either with the response forcibly prevented or with CS termination noncontingent on the response. A variety of theories has emerged to explain the efficacy of these techniques. As is demonstrated, these theories vary in their ability to accommodate the evidence on dissociation between fear and avoidance responding. No one of these theories can adequately account for all of the relevant data.

The Role of Fear Extinction in Theories of Flooding

Two-Process Fear Extinction Theory

Two-process theory in its various forms predicts that response prevention or flooding techniques should be effective in hastening extinction of avoidance responses. By the two-process account, flooding techniques that allow extended nonreinforced exposure to the CS should assure extinction of the fear CR, thus eliminating both the motivation and the reinforcement for continued responding.

The evidence relevant to this traditional two-process account is mixed. The discussion of this evidence is organized around three general, sometimes overlapping questions. First, to what extent is fear extinction necessary and/or sufficient for a flooding effect? Second, which results of response prevention experiments are difficult to accommodate within a two-process framework? And third, what evidence exists that some process other than fear extinction must also be operating during flooding?

Is fear extinction necessary and/or sufficient? Perhaps the most obvious attempt to demonstrate that fear extinction during flooding is not necessary for avoidance extinction is that of Marrazo, Riccio, and Riley (1974). They argue that fear extinction cannot account for flooding results because a group in their experiment that received reinforced CS presentations during flooding extinguished as rapidly as a group that received nonreinforced CS presentations. Fear could not have extinguished in the former group, so the effect of flooding was not solely attributable to Pavlovian fear extinction. There are, however, two problems with this interpretation. First, Bersh and Miller (1975) showed that Marrazo et al.'s results were due to their use of long (5-sec) shocks during flooding. These long shocks seemed to result in jumping and rearing behavior being conditioned to the situation, which in turn facilitated extinction by serving as incompatible responses. It is important to emphasize, however, that this is not the same process as that involved in regular flooding. When they gave short ($\frac{1}{2}$-sec) shocks during flooding, the avoidance responses were much slower to extinguish than with regularly flooded animals. Second, there are some logical problems with Marrazo et al.'s conclusions. That their two groups (fear conditioning and fear extinction) showed equally rapid extinction of the avoidance response does not imply that they did so for the same reason. Their results show at most that fear extinction is not necessary for avoidance extinction, but it may well be sufficient and may even be a necessary part of the traditional flooding process.

Presenting further problems to a two-process account, a number of investigators have noted that fear of the CS remains following extinction after flooding. Page (1955) and Coulter et al. (1969) showed that rats that reach an extinction criterion following response prevention in a one-way shuttlebox show greater fear of the safe side, as indexed by a passive avoidance test, than do rats reaching the same extinction criterion following a regular extinction procedure. Linton, Riccio, Rohrbaugh, and Page (1970) later demonstrated that a group receiving the response blocking procedure shows a small decrement in fear as compared to nonblocked,

nonextinguished controls, but rats that had received blocking and extinction trials showed even less fear, and rats that had been extinguished in the regular fashion showed the least fear.

There are, however, several reasons why these results of Coulter et al. (1969) and Linton et al. (1970) alone may not destroy the fear extinction account of flooding. First, Mackintosh (1974) has suggested that perhaps only a certain threshold amount of fear must be elicited to motivate an active avoidance response. Flooding may reduce the level of fear below this critical threshold but not enough to abolish fear, as indexed on a passive avoidance test. A recent experiment partially consistent with this idea has been reported by Monti and Smith (1976). They found that flooded rats demonstrated less fear of the CS, as indexed by a CER test, than did control rats who had spent a comparable amount of time in the home cage. The flooded rats did not, however, show zero levels of fear, and the difference between the two groups was significant for only the first three trials of the CER test (see also Corriveau & Smith, 1978). More definitive support for Mackintosh's idea would be provided by a demonstration that this amount of flooding was sufficient to rapidly extinguish the rats' avoidance response as compared to the effect of the home cage control treatment on the avoidance response. Such a demonstration is necessary because recent results of Mineka and Gino (1979a) indicate that an amount of flooding sufficient to reliably hasten the extinction of a well-learned shuttlebox avoidance response (20 trials) is not sufficient to reduce fear of the CS. A greater amount of flooding (30 vs. 20 trials) does reliably hasten avoidance extinction and reduce fear of the CS (Mineka & Gino, 1979a). At present, then, there is no good evidence to support Mackintosh's threshold idea: Fear extinction may occur during flooding, but it does not appear to be necessary for avoidance response extinction.

There is, however, a second reason why the Coulter et al. (1969) and Linton et al. (1970) results alone do not destroy the fear extinction account of flooding. Shipley, Mock, and Levis (1971) have criticized the Coulter et al. and Linton et al. experiments because total nonreinforced exposure to the CS was vastly different in blocked, blocked-then-extinguished, and normally extinguished groups. Their results suggest that when amount of nonreinforced CS exposure is held constant, residual fear, as indexed by a passive avoidance test, does not differ across blocked and nonblocked regularly extinguished groups. Furthermore, they found that total CS exposure time was similar in blocked and nonblocked groups when the extinction criterion was finally met. They interpret these results as supporting the two-process explanation that response prevention produces its effect through fear extinction. Baum (1971) also showed that flooded and nonflooded groups that had reached the same extinction criterion recovered equally from extinction when a loud buzzer was presented. He took this to indicate that residual fear in all groups following extinction was roughly equivalent, thereby contradicting Coulter et al.'s conclusion. There are as yet no experiments using CER as an index of fear that compare residual fear in blocked-then-extinguished and regularly extinguished groups. Such experiments are necessary before any definitive conclusions can be reached regarding amounts of residual fear following flooding versus conventional extinction procedures. Shipley et al.'s use of a passive avoidance test as an index of fear confounds behavioral passive avoidance with fear in a situation in which the two groups have had differential opportunity for such behavior to have been reinforced, and Baum's recovery procedure is hardly a validated index of fear. (See also Corriveau & Smith, 1978, for a more complete discussion of these issues.)

Berman and Katzev (1972) have also shown the importance of nonreinforced CS exposure in an experiment that equated CS exposure across five groups. Four groups received one of four different flooding treatments, each following two sessions of two-way shuttlebox avoidance acquisition. The fifth CS-time-control group received as many trials of response-contingent CS termination as were necessary to equate total CS exposure during this treatment phase to that

in the four flooded groups. This latter CS-time-control group extinguished faster than a nontreated control group and did not differ significantly from two of the four flooded groups. (The two groups whose responses were blocked during treatment extinguished faster than the two groups for whom responses were allowed but for whom CS termination was not response contingent.) Berman and Katzev point out that these results suggest that caution is necessary in interpreting the results of nearly all response prevention experiments in which total nonreinforced CS exposure is confounded with the response prevention procedure itself.

The Monti and Smith (1976), Shipley et al. (1971), and Berman and Katzev (1972) results do counter some of the arguments against the fear extinction account of flooding made by Page (1955), Coulter et al. (1969), and Linton et al. (1970) who all found differences in residual fear in flooded and regularly extinguished animals. These results all suggest that total nonreinforced CS exposure—which presumably allows for fear extinction to occur—may be the crucial variable in producing rapid extinction of avoidance. It must be emphasized, however, that this conclusion is based on the as yet unsupported assumption that the amount of fear extinction of an avoidance CS is directly related to the amount of nonreinforced CS exposure. Shipley (1974) did report that this is the case for straightforward fear conditioning and extinction. However, as yet no one has studied this issue directly in the avoidance/flooding situation, that is, whether fear extinction of an avoidance CS (as measured by a CER test) is a simple function of total amount of nonreinforced CS exposure. The results of Starr and Mineka (1977) indicate that the dynamics of fear conditioning in the avoidance situation are not identical to those in a more straightforward fear conditioning situation (cf. Starr & Mineka's yoked groups). In addition, Monti and Smith found that response prevention was more effective in eliminating fear conditioned in a classical paradigm than in eliminating fear conditioned over the course of avoidance learning. And perhaps most important are the results of Mineka and Gino (1979a) which indicate that with a large amount of CS exposure (600 as opposed to 400 sec), the forced aspect of the flooding procedure is more effective in reducing fear of the CS than is an equal amount of the self-exposure that occurs in traditional extinction. So caution is clearly necessary in extrapolating from results which indicate that nonreinforced CS exposure is directly related to avoidance response extinction (Berman & Katzev, 1972; Shipley et al., 1971) to the conclusion that fear extinction is mediating that extinction of the avoidance response. (See also the paradox discussed later presented by the Berman & Katzev, 1972, and Shipley et al., 1971, results.) Such caution seems particularly important given the results of Mineka and Gino (1979a) which indicate that fear as indexed by CER suppression does not diminish, given an amount of flooding that reliably hastens extinction of the avoidance response. Overall, the weight of the evidence seems to indicate that fear extinction is not a necessary part of flooding for avoidance response extinction, although given the results discussed so far, it may well be sufficient.

Other problems for a two-process fear extinction account. A number of other experiments have been considered by some reviewers such as Baum (1970b) to raise problems for the two-process account of flooding. For example, Benline and Simmel (1967) have results which suggest that the effects of flooding procedures may produce only temporary decrements in avoidance responding, perhaps through the learning of competing responses rather than through the extinction of fear. In their experiment, rats that had received 40, 80, or 160 blocking trials over a 5-day period showed response decrements on the first few sessions of extinction as compared to a nonblocked control group. By the 4th and 5th day of extinction, however, the blocked groups were responding as fast and as often as the nontreated control group. These results are difficult to interpret, though, because the control group itself showed no signs of extinction over 5 days (a questionable result considering that there had been only 50 acquisition trials on the 1st day). This makes the meaning of any spontaneous recovery in the blocked groups unclear.

Other experiments (e.g., Polin, 1959; Shearman, 1970) have also given multiple extinction sessions, and they did not see this pattern of spontaneous recovery in flooded groups. Actually, there is no a priori reason why spontaneous recovery of the avoidance response, even if it were convincingly demonstrated, should provide strong evidence against a two-process account of flooding. Spontaneous recovery of any conditioned response can be expected to occur following extinction (Kimble, 1961; Pavlov, 1927). If the conditioned fear response shows spontaneous recovery, then the avoidance response might be expected to recur also.

Potentially more damaging to a two-process account of flooding are the results reported by Werboff, Duane, and Cohen (1964). These investigators found a dissociation between autonomic (heart rate) indices of fear and avoidance responding; rats that had undergone a treatment similar to flooding showed greatly elevated heart rates, even though they were no longer responding. Although Rescorla and Solomon's (1967) version of two-process theory attempts to get around the problem of dissociation between peripheral and other indices of fear by postulating that fear is a central state, their theory has not been taken to postulate that peripheral indices can exist in the absence of the central state (although the reverse can be true) as the Werboff et al. data indicate. At a minimum these data extend the observations of dissociation between fear and avoidance following flooding to include such peripheral (psychophysiological) indices of fear.

Two other lines of research present problems to a two-process account of flooding because the results cannot easily be explained by a two-process account. Lederhendler and Baum (1970) reported that mechanical disruption of their rats' behavior during flooding (when abortive avoidance responses and freezing were occurring) greatly enhanced the efficacy of the flooding treatment as compared to the efficacy of the flooding for normally flooded animals. They interpret their results as supporting relaxation theory discussed later and point out that a two-process account has difficulty explaining the results. Furthermore, Baum (1970a) found that a loud buzzer during flooding enhances the efficacy of the flooding treatment. Since a loud buzzer should, if anything, increase the ambient level of fear, a two-process account of flooding has difficulty explaining why a loud buzzer enhances efficacy of the treatment. It may be that an increase in the ambient level of fear produced by a loud buzzer enhances the efficacy of flooding by habituating the animal to the state of fear itself rather than by extinction of the fear CR. (See Watson & Marks, 1971, for a similar argument for humans.) Baum (1970a) himself argues for a distraction interpretation of the results, which is orthogonal to a two-process account.

Evidence for another process other than fear extinction. Overall, the above experiments indicate that a two-process account of flooding does not account convincingly for all of the relevant data and that fear extinction is not a necessary part of flooding. But even if total nonreinforced CS exposure were the critical variable, as Shipley et al. (1971) and Berman and Katzev (1972) have suggested, a paradox more damaging to the two-process account than the experiments discussed above remains to be resolved: If flooded animals have had more CS exposure and therefore more extinction of the fear CR, then they should (and do) stop responding sooner than nonflooded animals. But if, as Berman and Katzev suggest, extinction of the avoidance response is solely a function of extinction of the fear CR, which in turn is solely a function of total nonreinforced CS exposure, then groups that have met the same extinction criterion should have done so because their fear CR has extinguished equally. This should occur regardless of whether the response has extinguished following flooding or following conventional extinction procedures. Yet the Page (1955), Coulter et al. (1969), and Linton et al. (1970) studies have indicated that groups reaching the same extinction criterion do not demonstrate equal amounts of the fear CR. Their flooded groups may indeed have had less CS exposure and therefore more residual fear than their nonflooded group (cf. Shipley et al., 1971), but their avoid-

ance response did extinguish. Again we see that although complete fear extinction may be sufficient for avoidance response extinction, it does not appear to be necessary. Some other form of learning in addition to extinction of the fear CR must generally also occur during flooding and contribute to rapid extinction of the avoidance response.

Even Berman and Katzev (1972) have some evidence indicating that Pavlovian fear extinction is probably not all that occurs during flooding. Their blocked-spaced trial group did extinguish significantly faster than their CS time control group, which indicates that some other kind of learning occurred in the former group. So if Pavlovian extinction of the fear CR cannot explain all of the relevant data on flooding, what other kind of learning can be taking place during flooding that could account for its efficacy in hastening avoidance extinction?

The safety signal revision of two-process theory must argue that the positive reinforcing properties of the response as a CS− extinguish during flooding. The avoidance response cannot be made during flooding, so reinforcement no longer occurs in the avoidance apparatus. This theory predicts that a CS− established during avoidance learning would no longer serve as a positive reinforcer if the effects were measured following flooding (as contrasted to the results of Weisman and Litner, 1969, when the effects of the CS− were measured before any flooding or extinction trials). No such evidence exists, so the adequacy of this account of flooding cannot be assessed. Some theorists (e.g., Seligman & Johnston, 1973) have even argued that safety signal theory cannot predict that flooding should work because if the response does not occur, how could the CS− properties of its feedback ever extinguish? Furthermore, the complex changes in fear that occur during flooding are of little interest to safety signal theorists because fear is not involved in asymptotic avoidance according to this theory.

Competing-Response Theory

Page (1955), Coulter et al. (1969), and Linton et al. (1970) have argued that what is learned during flooding is a response competing with that learned during acquisition: "Since CS onset results in a fear response which is reduced by fear offset, then any response *S* makes when the CS is terminated will be adventitiously reinforced" (Coulter et al., 1969, p. 380). Although these investigators stay within a two-process framework, the emphasis has changed from what happens to the Pavlovian fear CR to what happens to the instrumental response made to reduce that fear CR. This theory nicely explains the dissociation between the fear CR and avoidance responding. Furthermore, Shipley et al. (1971) have noted that blocked groups show lower activity levels than do nonblocked groups. Shearman (1970) has also noted that all of the 15 of his 40 flooded animals who made no responses over 9 days of extinction also made no intertrial interval responses, which thus indicates low activity levels. These low activity levels could indicate that freezing has become the "competing response." The Marrazo et al. (1974) and Bersh and Miller (1975) experiments discussed previously certainly indicate that competing responses learned during flooding can mediate the extinction of avoidance responding. No experiment has conclusively demonstrated, however, that competing responses either do mediate extinction or are necessary for such extinction. It should be noted that this conclusion is in the same vein as that reached regarding the necessity of Pavlovian fear extinction. As demonstrated earlier, even those experiments (e.g., Bersh & Paynter, 1972) purporting to demonstrate that fear extinction must contribute to avoidance extinction remain inconclusive because the Page (1955), Coulter et al. (1969), Linton et al. (1970), and Mineka and Gino (1979a) data still stand: Without much fear extinction, the avoidance response can extinguish. Analogously here, Black's (1958, 1959) results from flooding done under curare seem to show that a learned competing response is not necessary for extinction to occur: Dogs given no opportunity to learn a competing motor response because they were paralyzed by curare when flooding

was carried out still showed rapid avoidance response extinction.

Relaxation Theory

Baum (1970b) has criticized the competing-response theory on several different counts. His own experiments indicate that "undifferentiated exploratory behavior and grooming" (1970b, p. 281) tend to replace the extinguished avoidance response rather than any specific response such as crouching or freezing. In addition, he notes that a competing-response hypothesis has difficulty explaining why higher shock intensity and overtraining decrease the efficacy of a fixed amount of flooding. One could argue that a better learned avoidance response has more difficulty being overcome by a competing response, but one could also predict that adventitious reinforcement for a competing response in groups trained with higher shock intensity should be greater, thus increasing the efficacy of flooding. Baum's own analysis of what happens during flooding is that the animal learns to relax in the presence of the CS, an idea stemming from Denny's (1971) relaxation theory of avoidance learning. Evidence consistent with Baum's relaxation theory has been provided recently by Hawk and Riccio (1977). These investigators reasoned that if relaxation responses are responsible for avoidance extinction, then a technique that hastens the emergence of relaxation responses should enhance the efficacy of flooding. They presented an independently established CS− (presumably an elicitor of relaxation responses) during flooding for one group, and they did find more rapid extinction in that group. Unfortunately for Baum's theory, a group that received a novel CS during flooding showed rates of extinction comparable to those of the CS− group.

Actually, this relaxation account is similar to the fear extinction account of flooding, except that Baum (1970b) requires that the animal's normal, nonfearful behavioral repertoire (i.e., relaxation responses) return before one assumes that fear has extinguished. Hence the problems with this account are the same as those discussed previously regarding the fear extinction account. Baum (1970b) himself admits that his relaxation theory "still fails to explain evidence of fear (and no relaxation) following response prevention, even though the avoidance response has been extinguished" (p. 282). Furthermore, Morokoff and Timberlake (1971) have results which indicate that relaxation responses are at least not necessary for rapid extinction to occur. Their group that showed the most rapid avoidance response extinction showed six times as many fear responses (evidence of nonrelaxation) as did a group that extinguished substantially more slowly.

Baum concluded his review (1970b) of the three main accounts of flooding by stating that no one of these three accounts seems to explain all the relevant experiments and that all three accounts may be partially correct. His conclusion still stands. In addition, Baum points out that the process most involved in a given experiment (Pavlovian fear extinction, competing-response learning, or active relaxation) may depend on what particular parameters and procedures are used. More direct support of this point is given later.

Cognitive Theory

Another account of how flooding produces its effect has recently emerged as part of Seligman and Johnston's (1973) comprehensive cognitive theory of avoidance learning based on Irwin's (1971) cognitive theory of motivation. As discussed earlier, in this theory conditioned fear plays a role only in the acquisition of the avoidance response; in the well-maintained response, fear no longer plays a motivating role but is replaced by expectancies that responding produces no shock and that not responding is followed by shock and by a preference for no shock as compared to shock. The extreme persistence of avoidance responding in extinction is easily explained by this theory because fear may extinguish without a change in the expectancies that responding is necessary to avoid shock. Typically, the animal does not wait around long enough in the presence of the CS to have its expectancies disconfirmed. According to this cognitive theory of avoid-

ance, flooding hastens extinction of the avoidance response because the animal's expectancy that not responding will lead to shock is disconfirmed, and the more disconfirmation the animal receives, the faster it should stop responding. Seligman and Johnston claim that this theory can easily account for the previously discussed dissociation between extinction of fear and extinction of the avoidance response because disconfirmation of the expectancies governing responding could occur faster than Pavlovian fear extinction. Thus, as in the competing-response account, the emphasis here is that the response may change (i.e., extinguish) in the absence of any change in the level of fear.

At first glance, the attractiveness of this cognitive account of flooding lies in its ability to explain virtually any outcome of a flooding experiment; because extinction of conditioned fear is neither necessary nor sufficient for extinction of the avoidance response, the theory can predict either more or less fear in blocked as compared to normally extinguished groups. The fact that results indicate, if anything, more fear in blocked than in nonblocked groups presents no problem to the account, but neither would the opposite results. Failure of flooding to produce rapid extinction can be attributed to insufficient disconfirmation of the governing expectancies. However, here also lies the problem with this cognitive account of flooding. Because there is no independent way of measuring the governing expectancies, the cost of this flexibility is that it makes this theory impossible to test. This is orthogonal to any criticism of the cognitive theory of avoidance learning as a whole because most existing data on avoidance seem to be interpretable within the theory. (But see earlier discussion of Starr & Mineka, 1977, for one exception.) It certainly does detract, however, from its usefulness as an alternative to other current accounts of how flooding works.

Although formally the cognitive theory of avoidance learning is different from the discrimination theory of D'Amato (1970) and Herrnstein (1969), the latter theory's account of flooding would probably be similar; flooding would probably be seen as working by facilitating a detection of the change in reinforcement contingencies between acquisition and extinction. Additionally, the response might be thought to extinguish because it no longer brings reinforcement in the presence of the S^D. No predictions about fear or fear extinction during flooding would be made. The problems with this account are similar to those with the cognitive account: There is no independent way of assessing whether an amount of flooding that was insufficient to reduce resistance to extinction had failed because the response still produced reinforcement in the presence of the S^D.

Summary

Four accounts of how flooding hastens extinction of avoidance responses have been discussed. None is completely adequate. It is important to recognize that different learning processes may underlie the flooding effects with different kinds of avoidance responses. In particular, fear extinction may be more central to the extinction of some avoidance responses than to others. The myriad of experiments investigating flooding have involved not only different species (dogs for Black, 1958; Carlson & Black, 1959; Solomon et al., 1953; rats for all other studies) and different responses (one-way shuttlebox, jump-up box, two-way shuttlebox) but also responses trained to vastly different criteria (varying from three consecutive avoidance responses with less than 10 training trials to several hundred training trials over many days). In general, experiments taken to support two-process fear extinction accounts have used fairly well-learned two-way shuttlebox responses (e.g., Berman & Katzev, 1972; Monti & Smith, 1976; Polin, 1959; Shearman, 1970; but Mineka & Gino, 1979a, is an exception). Experiments taken to support competing-response accounts have generally used less well-learned one-way shuttlebox responses (e.g., Coulter et al., 1969; Linton et al., 1970; Page, 1955). Baum (1970b) has used moderately well-learned jump-up box responses to support his relaxation theory. Thus direct comparisons among these ex-

periments must be made with extreme caution. Baum has suggested that which account of flooding is most applicable may depend on the particular avoidance response being studied as well as the particular parameters of acquisition, shock intensity, and so forth. With special regard to understanding the dissociation between fear and avoidance, it is important to determine the extent of such dissociation following flooding of different avoidance responses.

The hypothesis that different learning processes mediate flooding effects in different avoidance situations may seem unnecessarily complicated. However, there are other indications of the different natures of two-way shuttlebox learning and one-way or jump-up box learning (e.g., Bolles, 1970; Seligman, Maier, & Solomon, 1971; Stampfl & Levis, 1973; Turner & Solomon, 1962). Bolles (1970), for example, has shown that the CS termination contingency (the source of fear reduction in traditional two-process theories and the source of informational feedback in more recent theories) is not important in one-way avoidance responding, although it is important in two-way shuttlebox responding. Levis and Stampfl (1972) and Stampfl and Levis (1973) have shown that responding to a serial CS is different in the one-way and the two-way situations. In a one-way apparatus, rats respond primarily to the first segment of a CS, although fear of the final segment is higher (Boyd & Levis, 1976). In the two-way shuttlebox, by contrast, rats respond primarily to the second segment of a serial CS. Seligman et al. (1971), in accounting for the failure to demonstrate learned helplessness in the one-way situation, point to the fact that one-way learning can be place learning, whereas two-way shuttlebox learning must of necessity be response learning. With these facts in mind, the idea that different learning processes may mediate the flooding effect in one-way and two-way situations seems reasonable. In two-way response-learning situations, any learning process that affects the motivation or reinforcement for responding (e.g., Pavlovian fear extinction and removal of the response/CS termination contingency) may well be sufficient to hasten extinction of the response. Whether fear extinction is necessary is much less clear given the results of Mineka and Gino (1979a). In the one-way situation, by contrast, reducing the motivation for responding or the response/CS termination contingency during flooding may not even be sufficient to hasten extinction of the response. If, as Seligman et al. (1971) and Bolles (1970) suggest, "running [or jumping] from a dangerous place to a safe place [is] an *innate* response" (Seligman et al., 1971, p. 370), then the animal may need either to learn a competing response or to actively relax in the formerly dangerous place or to have a cognitive change in its expectancy as to what is a safe place. So for one-way responses, fear extinction may be neither necessary nor sufficient for avoidance response extinction.

Nonspecificity of Flooding Effects and Implications for Theories of Flooding

Although there are major differences among the four major theories of flooding, they do have certain elements in common. The Pavlovian fear extinction account and the learned competing-response account are both embedded in a two-process framework, although they differ on which of the two processes is affected during flooding. The relaxation account is similar to the Pavlovian fear extinction account, except that it requires that the animal's normal nonfearful behavioral repertoire have returned before fear is acknowledged to have extinguished. The notion of learning to relax, reminiscent of Wolpe's (1958) reciprocal inhibition theory in which relaxation is learned as a response to previously fear-evoking stimuli also has features in common with a learned competing response, albeit of a different sort than that specified by Page (1955) and Coulter et al. (1969). In addition, the cognitive account has similarities to the competing-response account in that although fear may remain, the response made in the presence of that fear changes, either because of a change in act-outcome expectancies or because of adventitious reinforcement for the new response.

In addition to the above common points, all

four accounts share an implicit assumption that the effects of flooding should be quite specific (Bersh & Keltz, 1971). This specificity should manifest itself in two ways. First, because all four theories are associative in nature, they are silent on the issue of how nonassociative changes could be involved in flooding effects. Second, they all predict that the effects of a flooding treatment should be relatively specific to the avoidance response that has been flooded, that is, they do not predict that a flooding treatment applied to one avoidance response could have transsituational effects, such as hastening the extinction of a second avoidance response learned to a different CS. Both of these assumptions have been challenged recently.

Problems for the first aspect of the specificity assumption are best illustrated by a recent set of experiments reported by Crawford (1977). Crawford found that confinement in novel or fearful places produced nearly as large a facilitation of jump-up response extinction as did a response prevention procedure. She argues that these results are best explained by a species-specific defense response (SSDR) account of flooding (Bersh & Keltz, 1971). This account bears some resemblance to the competing-response account, except it emphasizes that the new response emerges spontaneously when the dominant SSDR is punished or suppressed, not as a result of adventitious reinforcement, that is, it is essentially a nonassociative account of flooding (Bolles, 1972). By this account, during response prevention as well as during confinement in a novel or fearful place, freezing becomes the dominant SSDR, and so when extinction of the avoidance response begins, freezing replaces jumping or fleeing as the dominant response.

Two other lines of evidence also suggest that nonassociative changes, such as a change in the SSDR hierarchy, produce effects that look much like traditional flooding effects. This questions the extent to which flooding acts via associative changes. Baum and LeClerc (1974) found that an irrelevant stress procedure—requiring rats to swim for 5 minutes—produced as large an effect on avoidance extinction as did a regular response prevention procedure. In addition, Monti and Smith (1976) reported that confinement in a shuttlebox alone, with no CS presentations, produced as large an effect on fear (CER) extinction as did a traditional flooding procedure. Together these results suggest that nonassociative changes—perhaps a change in SSDR hierarchy—can produce effects that appear identical to flooding effects.

There is one serious problem, however, in extending this conclusion to the degree that Crawford (1977) has done: Showing that a change in SSDR hierarchy can produce floodinglike effects does not mean that flooding normally acts via this process. For example, Baum and LeClerc (1974) went on to show that their irrelevant stress procedure probably did not produce its effect through the same process as did the response prevention procedure. When a 2-hour time delay was interpolated between the treatment procedures and extinction, the irrelevant stress procedure no longer had an effect, although the response prevention procedure did. This would be expected if irrelevant stress produces its effect through temporary nonassociative changes. Neither Crawford nor Monti and Smith (1976) ran such time delay groups to determine whether their nonspecific procedures were as effective after a delay as were their traditional flooding procedures. So, although there is some indication that nonassociative changes can produce floodinglike effects, it is not yet clear to what extent similar nonassociative changes mediate the effects of conventional flooding procedures.

The second aspect of the specificity assumption mentioned above—that flooding one avoidance response should not hasten the extinction of a second response learned to a different CS—has also been challenged by a recent set of experiments reported by Mineka (1976). In her first experiment, Mineka examined the comparative effectiveness of relevant and irrelevant flooding in hastening the extinction of a two-way shuttlebox response. All rats were trained to perform two different avoidance responses—a one-way jump-up response with a tone CS and a two-way shuttlebox response with a light CS. Flooding the jump-up response hastened extinction of the

shuttlebox response to nearly as large an extent as did flooding the shuttlebox response itself. These results demonstrate that flooding one avoidance response can hasten the extinction of a different response learned to a different CS. In other words, the effects of a flooding experience can be more general than previously thought.

Mineka (1976) then asked whether generalization of fear extinction across CS modalities (Pavlov, 1927) could have mediated this irrelevant flooding effect. By this account, extinction of fear to the tone CS and/or jump-up box grid that occurs during jump-up box flooding generalizes to produce extinction of fear of the shuttlebox light CS and/or shuttlebox grid. This in turn could reduce the motivation for responding in the shuttlebox sufficiently to account for the more rapid rate of extinction in the irrelevant flood group as compared to the control groups. By this hypothesis, the effect of the irrelevant flooding treatment should be somewhat smaller than that of the relevant flooding treatment, and this effect was found. Extinction across CS modalities is not expected to be as complete as extinction of the CR that has actually undergone the extinction procedure (Konorski, 1948). Mineka reasoned that if this hypothesis were correct, then any fear extinction procedure for one CS should also hasten the extinction of the shuttlebox avoidance response, that is, flooding of an irrelevant avoidance CS would not be necessary to see the effect.

In a second experiment, Mineka (1976) found evidence to support this hypothesis. Two groups of rats were trained to perform a shuttlebox avoidance response and were given Pavlovian fear conditioning trials with a different CS in a jump-up box. One group also received fear extinction trials in the jump-up box, whereas the second group was returned to their home cages for a comparable amount of time. Both groups were then tested for extinction of the shuttlebox avoidance response. The fear conditioning and extinction group showed substantially faster extinction of the shuttlebox avoidance response than did the fear conditioning alone control group. So it seems that an irrelevant Pavlovian fear extinction process can mediate the extinction of the shuttlebox avoidance response. This suggests that the Pavlovian fear extinction that occurred during irrelevant flooding in the previous experiment may well be the factor that mediated shuttlebox extinction there also. Mineka (1976) concluded that these experiments suggest that generalization of extinction across CS modalities can mediate extinction of a shuttlebox avoidance response.

However, this conclusion that generalization of fear extinction across CS modalities mediated the irrelevant flooding effect is now questionable; more recent evidence from Mineka's laboratory described earlier (Mineka & Gino, 1979a) suggests that fear extinction does not mediate the relevant flooding effect. This raises the question of what is mediating the irrelevant flooding effect. Mineka (1974, 1976) rejected on a variety of empirical and theoretical grounds the competing-response, relaxation, and cognitive accounts of flooding as explanations for this effect. Crawford's (1977) SSDR hypothesis, however, provides a possible explanation of this irrelevant flooding effect that is worthy of investigation. This hypothesis would state that the irrelevant flooding procedure acts in the same way as does relevant flooding or confinement in fearful places—by producing a change in the dominant SSDR from fleeing to freezing.

There is one major weakness in the SSDR hypothesis that must be investigated before its feasibility can be determined. Mineka (1976) found in a third experiment that irrelevant flooding did not hasten jump-up box extinction, that is, there is an asymmetry to her irrelevant flooding effect. Yet the SSDR hypothesis originated from results with jump-up extinction, so irrelevant flooding should hasten jump-up extinction. There are two possible resolutions of this apparent paradox. First, the irrelevant flooding experiments used a better trained jump-up response than did the brief confinement experiments, and the confinement effect may only occur with less well-learned responses. Second, the brief confinement experiments used a different extinction procedure than did the irrelevant flooding experiment. In the former experiments the ani-

mals started extinction on the grid floor, and if they had any tendency to freeze, there was nothing to break up that tendency; by continuing to freeze they could rapidly meet the extinction criterion. Mineka, by contrast, used Baum's (1970a, 1970b) procedure, in which the animals are dumped off the safety ledge at the start of the first extinction trial. This dumping procedure may break up any tendency for freezing (perhaps it is even a mild punishment for freezing.) Hence any change in SSDR hierarchy that may have occurred during flooding or confinement in novel places might be reversed. The feasibility of these explanations can be determined by experiments designed to test whether the brief confinement effect occurs with the Baum/Mineka (ledge) extinction procedure and whether Mineka's irrelevant flooding procedure hastens jump-up extinction if the grids extinction procedure is used. (See Mineka & Gino, 1979b, for results which indicate that the effect of confinement in novel or fearful places does not occur either when the ledge extinction procedure is used or when the grids extinction procedure is used with a better learned response such as that used by Mineka, 1976).

In sum, there are several aspects to the nonspecificity of flooding, but the implications of findings in this area for our understanding of what goes on during traditional flooding procedures are as yet unclear. First, confinement in novel, fearful, or stressful places can produce floodinglike effects, but the extent to which these nonassociative effects contribute to traditional response prevention effects is unknown. It is unlikely, given Baum and LeClerc's (1974) time delay results as well as the results of Mineka and Gino (1979b), that purely nonassociative changes account for all of the effects of response prevention. Second, the effects of flooding one avoidance response can have transsituational effects and hasten the extinction of a second response that was learned to a different CS, but it is not yet known whether this irrelevant flooding effect is mediated by associative factors (e.g., generalization of extinction across CS modalities) or by nonassociative factors such as those suggested by Crawford's (1977) hypothesis.

The Role of Fear in Alternative Extinction Procedures for Avoidance

In recent years the conventional extinction procedure used to study the persistence of avoidance responses has received a substantial amount of criticism. In studies of the extinction of appetitive responses, the positive reinforcer—food or water—has traditionally been withheld. Analogously, it became common practice many years ago to withhold the negative reinforcer—shock—in studies of the extinction of avoidance behavior. Thus during extinction, shocks are no longer presented if an animal fails to respond, but responses continue to produce CS termination. Because it is now accepted that either CS termination and/or shock avoidance per se maintain avoidance behavior (Katzev, 1972; Herrnstein, 1969; Mackintosh, 1974), it seems to some that extinction of avoidance should be studied either by removing the CS termination contingency and/or by removing the shock avoidance contingency. Davenport and Olson (1968) reported rapid extinction of a discriminative bar-press avoidance response when both these sources of reinforcement were removed. Reynierse and Rizley (1970) subsequently confirmed these results with a shuttlebox avoidance response; removing the CS termination contingency or presenting CSs and USs randomly were both more effective procedures for eliminating avoidance than was the conventional procedure. Bolles, Moot, and Grossen (1971) further parceled out the relative contributions of CS termination versus shock avoidance to the extinction of avoidance and concluded that the shock avoidance contingency was crucial in creating an avoidance response that is highly resistant to extinction. Animals receiving shocks either randomly during extinction or as punishment for avoidance responses showed rapid extinction of the avoidance response. CS termination proved to be important only as long as the responses continued to avoid shock. This last finding conflicts with the report of Katzev that CS termination is extremely important in maintaining avoidance responding at a high rate when an avoidance contingency is in effect. Katzev reports low rates of responding with delayed CS termination and shock avoidance; Bolles

et al., on the other hand, report relatively high rates of responding with delayed CS termination and shock avoidance.[2]

It is now clear that the extreme persistence of avoidance responses is largely a result of using the conventional extinction procedures in which both CS termination and shock avoidance continue to be sources of reinforcement for responding in extinction. Because maintenance of the response/reinforcement contingency is necessary for a response that is highly resistant to extinction, some theorists (e.g., Mackintosh, 1974) have concluded that the longstanding question wrestled over by learning theorists of how to explain the persistence of avoidance responses in the face of apparent nonreinforcement (i.e., no shock) is really a pseudoproblem. These arguments are well-founded insofar as they constitute a sound analysis of what the reinforcing events and response/reinforcement contingencies are in avoidance learning. Such arguments fail to recognize, however, that the conventional extinction procedure that produces such extreme persistence is still interesting in its own right.

Aronfreed (1968) has cogently argued that the process of a child's internalizing control over his/her own behavior closely parallels the learning and maintenance of avoidance responses as they have conventionally been studied in animals. He argues that the extreme resistance to extinction seen in animals' avoidance responses (e.g., Solomon et al., 1953) is analogous to the observation that behavioral changes that occur in the process of human socialization are also highly resistant to changes in external contingencies. Children and adults frequently persist in responses originally acquired under circumstances of aversive control even when the aversive outcomes would no longer occur. Aronfreed further contends that this is most likely to occur in cases in which a child never had a cognitive representation of the original contingencies and so is unlikely to become aware of a change in the contingencies. This is obviously parallel to the case in which an animal learns an avoidance response that persists when conventional extinction procedures are used because it never stays around long enough to sample or become aware of the new contingencies. The newer extinction procedures, discussed previously, which change the CS termination and/or shock avoidance contingencies, forcibly expose the animal to the change in contingencies; hence extinction proceeds at a much faster rate.

Therefore, we can conclude that the extreme persistence of avoidance responses may not be as surprising or puzzling as it was once conceived to be and yet still concede that the question of what learning processes underlie the ultimate extinction of these responses is still an important and interesting one. If we are interested in the natural course of extinction, given the original contingencies, the processes underlying flooding or response prevention techniques, which hasten extinction, also remain important topics of investigation. These techniques are particularly interesting in light of the parallel dissociations between fear and avoidance behavior, on the one hand, and between subjective, behavioral, and psychophysiological indices of fear in humans undergoing systematic desensitization or flooding therapy, on the other hand.

One interesting issue that has not yet been investigated is the extent to which the dissociation between fear and avoidance that is observed following flooding and conventional extinction procedures also occurs with the newer procedures that remove the CS termination and/or shock avoidance contingencies. Some evidence (e.g., Coulter et al., 1969; Linton et al., 1970) suggests that the learning processes underlying flooding are different than those underlying the conventional extinction procedures because different residual amounts of fear remain. Other evidence (e.g., Berman & Katzev, 1972), however, suggests that flooding and regular extinction act via the same underlying process—nonreinforced CS exposure, which produces fear extinction. Riccio and Silvestri (1973) have speculated that extinction procedures that remove the

---

[2] It should be noted that punishment of avoidance often results in increased rather than reduced resistance to extinction—the so-called vicious circle phenomenon. (For extensive reviews of the literature on the determinants of which result is likely to occur in a particular situation, see, e.g., Brown, 1969, and Mackintosh, 1974.)

response/CS termination contingency may be more effective in eliminating the "motivational" (i.e., fear-eliciting) properties of the CS than are conventional extinction or response-blocking procedures. There is no compelling evidence to support or refute this speculation at present. It is unlikely that removing the shock avoidance contingency (e.g., Davenport & Olson, 1968) could produce extinction by fear extinction. This procedure is more likely to produce its effect through learning of a competing response or by a change in response/outcome expectancies. Recently, in fact, Overmier and Brackbill (1977) demonstrated that an effective avoidance extinction procedure involving noncontingent US presentations leaves fear of the CS intact. They interpret their results in terms of the independence of CS-fear and fear-avoidance response links in the avoidance-learning situation (see also Overmier & Bull, 1969). The results can also be interpreted in terms of the dissociation between fear and avoidance responding discussed earlier. Further exploration of these different avoidance procedures is particularly important because learning theorists and behavior therapy researchers are beginning to speculate, on the basis of animal experiments, about which contingencies it is most important to remove during desensitization and flooding therapy in humans (e.g., Riccio & Silvestri, 1973; Wilson, 1973).

In sum, we can see that there are multiple ways of extinguishing an avoidance response. What factors these procedures have in common is not yet clear, although it seems certain that multiple learning processes are involved. Experiments designed to determine the degree of residual fear following these different procedures will be of particular interest.

Conclusion

Fear and fear extinction do not appear to play any simple role in avoidance acquisition, maintenance, and extinction. There is often a marked dissociation or desynchrony between fear and avoidance behavior, and the determinants of this dissociation are as yet poorly understood. Fear attenuates over the course of avoidance learning; yet this cannot be explained by simple Pavlovian fear extinction (Starr & Mineka, 1977). The question of what continues to motivate avoidance responding as fear diminishes remains a hotly debated issue (e.g., D'Amato, 1970; Herrnstein, 1969; Mackintosh, 1974; Seligman & Johnston, 1973). These new theories of avoidance have emerged in large part as a result of the inadequacies of traditional two-process theory in explaining the dissociation between fear and avoidance behavior. Each theory postulates some new mechanism to explain well-maintained avoidance responding and extinction of responding. In so doing, these theories have tended to ignore or treat in only a cursory fashion the interesting determinants of this dissociation. However, fear remains a salient feature of avoidance learning, and the question of what determines its course at various stages of avoidance acquisition, maintenance, and extinction remains one of great practical and theoretical importance, at least for those interested in general questions about the determinants of fear and fear extinction in more complex situations than those traditionally studied by theorists of classical conditioning.

The determinants of fear extinction and its role in mediating avoidance extinction and the effects of response prevention techniques are also complex. Fear extinction is certainly not a necessary precursor of avoidance response extinction. With some avoidance responses (e.g., two-way shuttlebox), fear extinction may be sufficient to cause avoidance extinction, whereas with others, fear extinction may not be sufficient (e.g., one-way responses). Further work is needed to clarify the situations in which fear extinction is more or less central to avoidance response extinction.

The dissociation between fear and avoidance responding often observed following flooding is of particular interest because it may be functionally analogous to the dissociation frequently seen among different elements of the phobic response following systematic desensitization and flooding therapy (e.g., Lang, 1968, 1971; Rachman & Hodgson, 1974; Riccio & Silvestri, 1973). For example, patients frequently report that they can approach their phobic object (i.e., the

avoidance component is gone) but that they still feel afraid of it (i.e., the subjective feeling of fear and sometimes the psychophysiological concomitants of this feeling are still present). Although conditioned avoidance responses are often considered to be a poor model for human phobias (e.g., Costello, 1970; Seligman, 1971), many of the same variables found to enhance the effectiveness of flooding are also found to be important in flooding therapy with humans. (See Baum, 1970b, and Marks, 1972, for reviews.) So further work on the determinants of fear extinction during flooding is important for our understanding not only of the role of fear in the extinction of avoidance but also of a number of analogous problems in human behavior therapy techniques.
